## Algorithms I

Markus Lohrey

Universität Siegen

Wintersemester 2017/2018

### Overview, Literature

#### Overview:

- Basics
- Oivide & Conquer
- Sorting
- Greedy algorithms
- Dynamic programming
- Graph algorithms

#### Literature:

- Cormen, Leiserson Rivest, Stein. Introduction to Algorithms (3. Auflage); MIT Press 2009
- Schöning, Algorithmik. Spektrum Akademischer Verlag 2001

## Landau Symbols

Let  $f, g : \mathbb{N} \to \mathbb{N}$  be functions.

- $g \in \mathcal{O}(f)$  if  $\exists c > 0 \ \exists n_0 \ \forall n \geq n_0 : \ g(n) \leq c \cdot f(n)$ . In other words: g is not growing faster than f.
- $g \in o(f)$  if  $\forall c > 0 \ \exists n_0 \ \forall n \geq n_0 : \ g(n) \leq c \cdot f(n)$ .

In other words: g is growing strictly slower than f.

- $g \in \Omega(f) \Leftrightarrow f \in \mathcal{O}(g)$ In other words: g is growing at least as fast than f.
- $g \in \omega(f) \Leftrightarrow f \in o(g)$ In other words: g is growing strictly faster than f.
- $g \in \Theta(f) \Leftrightarrow (f \in \mathcal{O}(g) \land g \in \mathcal{O}(f))$ In other words: g and f have the same asymptotic growth.

### Jensen's Inequality

Let  $f: D \to \mathbb{R}$  be a function, where  $D \subseteq \mathbb{R}$  is an interval.

- f is convex if for all  $x, y \in D$  and all  $0 \le \lambda \le 1$ ,  $f(\lambda x + (1 \lambda)y) \le \lambda f(x) + (1 \lambda)f(y)$ .
- f is concave if for all  $x, y \in D$  and all  $0 \le \lambda \le 1$ ,  $f(\lambda x + (1 \lambda)y) \ge \lambda f(x) + (1 \lambda)f(y)$ .

#### Jensen's inequality

If f is concave, then for all  $x_1, \ldots, x_n \in D$  and all  $\lambda_1, \ldots, \lambda_n \geq 0$  with  $\lambda_1 + \cdots + \lambda_n = 1$ :

$$f\left(\sum_{i=1}^n \lambda_i \cdot x_i\right) \ge \sum_{i=1}^n \lambda_i \cdot f(x_i).$$

If f is convex, then for all  $x_1, \ldots, x_n \in D$  and all  $\lambda_1, \ldots, \lambda_n \geq 0$  with  $\lambda_1 + \cdots + \lambda_n = 1$ :

$$f\left(\sum_{i=1}^n \lambda_i \cdot x_i\right) \leq \sum_{i=1}^n \lambda_i \cdot f(x_i).$$

# Complexity measures

We describe the running time of an algorithm A as a function in the input length n.

Standard: Worst case complexity

Maximal running time on all inputs of length n:

$$t_{A,\text{worst}}(n) = \max\{t_A(x) \mid x \in X_n\},\$$

where 
$$X_n = \{x \mid |x| = n\}.$$

Criticism: Unrealistic, since in practise worst-case inputs might not arise.

# Complexity measures

Alternative: average case complexity.

Needs a probability distribution on  $X_n$ .

Standard: uniform distribution, i.e.,  $Prob(x) = \frac{1}{|X_n|}$ .

Average running time:

$$t_{A,\varnothing}(n) = \sum_{x \in X_n} \operatorname{Prob}(x) \cdot t_A(x)$$

$$= \frac{1}{|X_n|} \sum_{x \in X_n} t_A(x) \quad \text{(for uniform distribution)}$$

Problem: Difficult to analyse

#### Example: quicksort

Worst case number of comparisons of quicksort:  $t_Q(n) \in \Theta(n^2)$ .

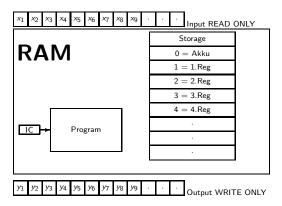

Average number of comparisons:  $t_{Q,\varnothing}(n) = 1.38n \log n$ 

## Machine models: Turing machines

The Turing machine (TM) is a very simple and mathematically easy to define model of computation.

But: memory access (i.e., moving head to a certain symbol on the tape) is very time-consuming on a Turing machine and not realistic.

# Machine models: Register machine (RAM)

Assumption: Elementary operations (e.g., the arithmetic operations  $+, \times, -$ , DIV, comparison, bitwise AND and OR) need a single computation step.

### Overview

- Solving recursive equations
- Mergesort
- Fast multiplication of integers
- Matrix multiplication a la Strassen

# Divide & Conquer: basic idea

As a first major design principle for algorithms, we will see Divide & Conquer:

#### Basic idea:

- Divide the input into several parts (usually of roughly equal size)
- Solve the problem on each part separately (recursion).
- Construct the overall solution from the sub-solutions.

## Recursive equations

Divide & Conquer leads in a very natural way to recursive equations.

#### Assumptions:

- Input of length n will be split into a many parts of size n/b.
- Dividing the input and merging the sub-solutions takes time g(n).
- For an input of length 1 the computation time is g(1).

This leads to the following recursive equation for the computation time:

$$t(1) = g(1)$$
  
$$t(n) = a \cdot t(n/b) + g(n)$$

Technical probem: What happens, if *n* is not divisible by *b*?

- Solution 1: Replace n/b by  $\lceil n/b \rceil$ .
- Solution 2: Assume that  $n = b^k$  for some  $k \ge 0$ .

If this does not hold: Stretch the input (for every n there exists a  $k \ge 0$  with  $n \le b^k < bn$ ).

# Solving simple recursive equations

#### Theorem 1

Let  $a,b \in \mathbb{N}$  and b > 1,  $g : \mathbb{N} \longrightarrow \mathbb{N}$  and assume the following equations:

$$t(1) = g(1)$$
  
$$t(n) = a \cdot t(n/b) + g(n)$$

Then for all  $n = b^k$  (i.e.,  $k = \log_b(n)$ ):

$$t(n) = \sum_{i=0}^{k} a^{i} \cdot g\left(\frac{n}{b^{i}}\right).$$

**Proof:** Induction over *k*.

$$k = 0$$
: We have  $n = b^0 = 1$  and  $t(1) = g(1)$ .

### Solving simple recursive equations

k > 0: By induction we have

$$t\left(\frac{n}{b}\right) = \sum_{i=0}^{k-1} a^{i} \cdot g\left(\frac{n}{b^{i+1}}\right).$$

Hence:

$$t(n) = a \cdot t \left(\frac{n}{b}\right) + g(n)$$

$$= a \left(\sum_{i=0}^{k-1} a^i \cdot g\left(\frac{n}{b^{i+1}}\right)\right) + g(n)$$

$$= \sum_{i=1}^k a^i \cdot g\left(\frac{n}{b^i}\right) + a^0 g\left(\frac{n}{b^0}\right)$$

$$= \sum_{i=0}^k a^i \cdot g\left(\frac{n}{b^i}\right).$$

### Master theorem I

#### Theorem 2 (Master theorem I)

Let  $a, b, c, d \in \mathbb{N}$  with b > 1 and assume that

$$t(1) = d$$
  
$$t(n) = a \cdot t(n/b) + d \cdot n^{c}$$

Then, for all n of the form  $b^k$  with  $k \ge 0$  we have:

$$t(n) \in \begin{cases} \Theta(n^c) & \text{if } a < b^c \\ \Theta(n^c \log n) & \text{if } a = b^c \\ \Theta(n^{\frac{\log a}{\log b}}) & \text{if } a > b^c \end{cases}$$

Remark:  $\frac{\log a}{\log b} = \log_b a$ . If  $a > b^c$ , then  $\log_b a > c$ .

### Proof of the master theorem I

Let  $g(n) = dn^c$ . By Theorem 1 we have the following for  $k = \log_b n$ :

$$t(n) = d \cdot n^{c} \cdot \sum_{i=0}^{k} \left(\frac{a}{b^{c}}\right)^{i}.$$

Case 1:  $a < b^c$ 

$$t(n) \leq d \cdot n^c \cdot \sum_{i=0}^{\infty} \left(\frac{a}{b^c}\right)^i = d \cdot n^c \cdot \frac{1}{1 - \frac{a}{b^c}} \in \mathcal{O}(n^c).$$

Moreover,  $t(n) \in \Omega(n^c)$ , which implies  $t(n) \in \Theta(n^c)$ .

Case 2:  $a = b^c$ 

$$t(n) = (k+1) \cdot d \cdot n^c \in \Theta(n^c \log n).$$

### Proof of the master theorem I

Case 3:  $a > b^c$ 

$$t(n) = d \cdot n^{c} \cdot \sum_{i=0}^{k} \left(\frac{a}{b^{c}}\right)^{i} = d \cdot n^{c} \cdot \frac{\left(\frac{a}{b^{c}}\right)^{k+1} - 1}{\frac{a}{b^{c}} - 1}$$

$$\in \Theta\left(n^{c} \cdot \left(\frac{a}{b^{c}}\right)^{\log_{b}(n)}\right)$$

$$= \Theta\left(\frac{n^{c} \cdot a^{\log_{b}(n)}}{b^{c \log_{b}(n)}}\right)$$

$$= \Theta\left(a^{\log_{b}(n)}\right)$$

$$= \Theta\left(b^{\log_{b}(a) \cdot \log_{b}(n)}\right)$$

$$= \Theta\left(n^{\log_{b}(a)}\right)$$

# Stretching the input is ok

Stretching the input length to a b-power does not change the statement of the master theorem I.

Formally: Assume that the function t satisfies the following recursive equation

$$t(1) = d$$
  
$$t(n) = a \cdot t(n/b) + d \cdot n^{c}$$

for all b-powers n.

Define the function  $s: \mathbb{N} \to \mathbb{N}$  by s(n) = t(m), where m is the smallest b-power with  $m \ge n \ (\rightsquigarrow n \le m \le bn)$ .

With the master theorem I we get

$$s(n) = t(m) \in \begin{cases} \Theta(m^c) = \Theta(n^c) & \text{if } a < b^c \\ \Theta(m^c \log m) = \Theta(n^c \log n) & \text{if } a = b^c \\ \Theta(m^{\frac{\log a}{\log b}}) = \Theta(n^{\frac{\log a}{\log b}}) & \text{if } a > b^c \end{cases}$$

### Master theorem II

#### Theorem 3 (Master theorem II)

Let r > 0,  $\sum_{i=0}^{r} \alpha_i < 1$  and assume that for a constant c,

$$t(n) \leq \left(\sum_{i=0}^r t(\lceil \alpha_i n \rceil)\right) + c \cdot n.$$

Then we have  $t(n) \in \mathcal{O}(n)$ .

### Proof of the master theorem II

Choose  $\varepsilon > 0$  and  $n_0 > 0$  such that

$$\sum_{i=0}^{r} \lceil \alpha_{i} n \rceil \leq \left( \sum_{i=0}^{r} \alpha_{i} \right) \cdot n + (r+1) \leq (1-\varepsilon)n$$

for all  $n > n_0$ .

Choose  $\gamma$  such that  $c \leq \gamma \varepsilon$  and  $t(n) \leq \gamma n$  for all  $n < n_0$ .

By induction we get for all  $n \ge n_0$ :

$$t(n) \leq \left(\sum_{i=0}^{r} t(\lceil \alpha_{i} n \rceil)\right) + cn$$

$$\leq \left(\sum_{i=0}^{r} \gamma \lceil \alpha_{i} n \rceil\right) + cn \qquad \text{(induction)}$$

$$\leq (\gamma(1-\varepsilon) + c)n$$

$$< \gamma n$$

### Mergesort

We want to sort an array A of length n, where  $n = 2^k$  for some  $k \ge 0$ .

### Algorithm mergesort

```
procedure mergesort(l, r)

var m: integer;

begin

if (l < r) then

m := (r + l) div 2;

mergesort(l, m);

mergesort(m + 1, r);

endif

endprocedure
```

### Mergesort

### Algorithm merge

```
procedure merge(I, m, r)
var i, j, k: integer;
begin
  i = I; i := m + 1;
  for k := 1 to r - l + 1 do
    if i = m + 1 or (i \le m \text{ and } j \le r \text{ and } A[j] \le A[i]) then
       B[k] := A[j]; j := j + 1
     else
       B[k] := A[i]; i := i + 1
     endif
  endfor
  for k := 0 to r - l do
    A[I + k] := B[k + 1]
  endfor
endprocedure
```

### Mergesort

Note: merge(l, m, r) works in time  $\mathcal{O}(r - l + 1)$ .

Running time:  $t_{ms}(n) = 2 \cdot t_{ms}(n/2) + d \cdot n$  for a constant d.

Master theorem I:  $t_{ms}(n) \in \Theta(n \log n)$ .

We will see later that  $\mathcal{O}(n \log n)$  is asymptotically optimal for sorting algorithms that are only based on the comparison of elements.

Drawback of Mergesort: no in-place sorting algorithm

A sorting algorithm works in-place, if at every time instant only a constant number of elements from the input array A is stored outside of A.

We will see in-place sorting algorithms with a running of  $\mathcal{O}(n \log n)$ .

# Multiplication of natural numbers

We want to multiply two *n*-bit natural numbers, where  $n = 2^k$  for some  $k \ge 0$ .

School method:  $\Theta(n^2)$  bit operations.

Alternative approach:

Here, A(C) are the first n/2 bits and B(D) are the last n/2 bits of r(s), i.e.,

$$r = A 2^{n/2} + B;$$
  $s = C 2^{n/2} + D$   
 $r s = A C 2^n + (A D + B C) 2^{n/2} + B D$ 

Master theorem I:  $t_{\text{mult}}(n) = 4 \cdot t_{\text{mult}}(n/2) + \Theta(n) \in \Theta(n^2)$ No improvement!

## Fast multiplication by A. Karatsuba, 1960

Compute recursively AC, (A - B)(D - C) and BD.

Then, we get

$$rs = AC2^{n} + (A - B)(D - C)2^{n/2} + (BD + AC)2^{n/2} + BD$$

By the master theorem I, the total number of bit operations is:

$$t_{\text{mult}}(n) = 3 \cdot t_{\text{mult}}(n/2) + \Theta(n) \in \Theta(n^{\frac{\log 3}{\log 2}}) = \Theta(n^{1.58496...}).$$

Using divide & conquer we reduced the exponent from 2 (school method) to 1.58496...

# How fast can we multiply?

In 1971, Arnold Schönhage and Volker Strassen presented an algorithm which multiplies two n-bit number in time  $\mathcal{O}(n \log n \log \log n)$  on a multitape Turing-machine.

The Schönhage-Strassen algorithm uses the so-called fast Fourier transformation (FFT); see Algorithms II.

In practice, the Schönhage-Strassen algorithm beats Karatsuba's algorithm for numbers with approx. 10.000 digits.

In 2007, Martin Fürer came up with an algorithm that beats the Schönhage-Strassen algorithm. His algorithm has a running time of  $\mathcal{O}(n \log n \ 2^{\log^* n})$ , where  $\log^* n$  is the first number k such that  $\log_2(\cdot) k$ -times applied to n yields a number  $\leq 1$ .

# Matrix multiplication using naive divide & conquer

Let  $A = (a_{i,j})_{1 \le i,j \le n}$  and  $B = (b_{i,j})_{1 \le i,j \le n}$  be two  $(n \times n)$ -matrices.

For the product matrix  $AB = (c_{i,j})_{1 \le i,j \le n} = C$  we have

$$c_{i,j} = \sum_{k=1}^{n} a_{i,k} b_{k,j}$$

 $\rightsquigarrow \Theta(n^3)$  scalar multiplications.

Divide & conquer: A, B are divided in 4 submatrices of roughly equal size. Then, the product AB = C can be computed as follows:

$$\begin{pmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{pmatrix} \begin{pmatrix} B_{11} & B_{12} \\ B_{21} & B_{22} \end{pmatrix} = \begin{pmatrix} C_{11} & C_{12} \\ C_{21} & C_{22} \end{pmatrix}$$

## Matrix multiplication using naive divide-and-conquer

$$\begin{pmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{pmatrix} \begin{pmatrix} B_{11} & B_{12} \\ B_{21} & B_{22} \end{pmatrix} = \begin{pmatrix} C_{11} & C_{12} \\ C_{21} & C_{22} \end{pmatrix}$$

where

$$C_{11} = A_{11}B_{11} + A_{12}B_{21}$$

$$C_{12} = A_{11}B_{12} + A_{12}B_{22}$$

$$C_{21} = A_{21}B_{11} + A_{22}B_{21}$$

$$C_{22} = A_{21}B_{12} + A_{22}B_{22}$$

We get

$$t(n) = 8 \cdot t(n/2) + \Theta(n^2) \in \Theta(n^3).$$

No improvement!

# Matrix multiplication by Volker Strassen (1969)

Compute the product of two  $2 \times 2$  matrices with 7 multiplications:

$$\begin{array}{llll} M_1 & := & (A_{12} - A_{22})(B_{21} + B_{22}) & C_{11} & = & M_1 + M_2 - M_4 + M_6 \\ M_2 & := & (A_{11} + A_{22})(B_{11} + B_{22}) & C_{12} & = & M_4 + M_5 \\ M_3 & := & (A_{11} - A_{21})(B_{11} + B_{12}) & C_{21} & = & M_6 + M_7 \\ M_4 & := & (A_{11} + A_{12})B_{22} & C_{22} & = & M_2 - M_3 + M_5 - M_7 \\ M_5 & := & A_{11}(B_{12} - B_{22}) & & & & & & \\ M_6 & := & A_{22}(B_{21} - B_{11}) & & & & & & \\ M_7 & := & (A_{21} + A_{22})B_{11} & & & & & & \\ \end{array}$$

Running time: 
$$t(n) = 7 \cdot t(n/2) + \Theta(n^2)$$
.

Master theorem I (
$$a = 7$$
,  $b = 2$ ,  $c = 2$ ):

$$t(n) \in \Theta(n^{\log_2 7}) = \Theta(n^{2,81...}).$$

### Overview

- Lower bounds for comparison-based sorting algorithms
- Quicksort
- Heapsort
- Sorting in linearer time
- Median computation

### Comparison-based sorting algorithms

A sorting algorithm is comparison-based if the elements of the input array belong to a data type that only supports the comparison of two elements.

We assume in the following considerations that the input array  $A[1, \ldots, n]$  has the following properties:

- $A[i] \in \{1, \ldots, n\}$  for all  $1 \le i \le n$ .
- $A[i] \neq A[j]$  for  $i \neq j$

In other words: The input is a permutation of the list [1, 2, ..., n].

The sorting algorithm has to sort this list.

Another point of view: The sorting algorithm has to compute the permutation  $[i_1, i_2, ..., i_n]$  such that  $A[i_k] = k$  for all  $1 \le k \le n$ .

**Example:** On input [2,3,1] the output should be [3,1,2].

### Lower bound for the worst case

#### Theorem 4

For every comparison-based sorting algorithm and every n there exists an array of length n, on which the algorithm makes at least

$$n \log_2(n) - \log_2(e)n \ge n \log_2(n) - 1,443n$$

many comparisons.

**Proof:** We execute the algorithm on an array A[1, ..., n] without knowing the concrete values A[i].

This yields a decision tree that can be constructed as follows:

Assume that the algorithm compares A[i] and A[j] in the first step.

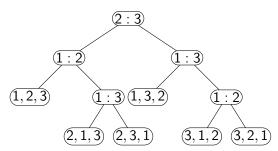

We label the root of the decision tree with i:j.

The left (right) subtree is obtained by continuing the algorithm under the assumption that A[i] < A[j] (A[i] > A[j]).

#### Lower bound for the worst case

This yields a binary tree with n! many leaves because every input permutation must lead to a different leaf.

**Example:** Here is a decision tree for sorting an array of length 3.

#### Lower bound for the worst case

**Note:** The depth (= max. number of edges on a path from the root to a leaf) of the decision tree is the maximal number of comparisons of the algorithm on an input array of length n.

A binary tree with N leaves has depth  $\geq \log_2(N)$ .

Stirling's formula (we only need  $n! > \sqrt{2\pi n}(n/e)^n$ ) implies

$$\log_2(n!) \ge n \log_2(n) - \log_2(e)n + \Omega(\log n) \ge n \log_2(n) - 1,443n.$$

Thus, there exists an input array for which the algorithm makes at least  $n \log_2(n) - 1$ , 443n many comparisons.

### Lower bound for the average case

A comparison-based sorting algorithm even makes  $n \log_2(n) - 2,443n$  many comparisons on almost all input permutations:

#### Theorem 5

For every comparison-based sorting algorithm the following holds: The portion of all permutations on which the algorithm makes at least

$$\log_2(n!) - n \ge n \log_2(n) - 2,443n$$

many comparisons is at least  $1 - 2^{-n+1}$ .

For the proof we need a simple lemma:

#### Lemma 6

Let  $A \subseteq \{0,1\}^*$  with |A| = N, and let  $1 \le n < \log_2(N)$ . Then, at least  $(1-2^{-n+1})N$  many words in A have length  $\ge \log_2(N) - n$ .

### Lower bound for the average case

Consider again the decision tree. It has n! leaves, and every leaf corresponds to a permutation of the numbers  $\{1, \ldots, n\}$ .

Thus, each of the n! many permutations can be represented by a word over the alphabet  $\{0,1\}$ :

- 0 means: go in the decision tree to the left child.
- 1 means: go in the decision tree to the right child.

Lemma 6  $\rightsquigarrow$  the decision tree has at least  $(1-2^{-n+1})n!$  many root-leaf paths of length  $\geq \log_2(n!) - n \geq n \log_2(n) - 2,443n$ .

## Lower bound for the average case

### Corollary

Every comparison-based sorting algorithm makes on average at least  $n \log_2(n) - 2,443n$  many comparisons when sorting an array of length n (for n large enough).

Proof: Due to Theorem 5 at least

$$(1-2^{-n+1}) \cdot (\log_2(n!) - n) + 2^{-n+1} = \log_2(n!) - n - \frac{\log_2(n!) - n - 1}{2^{n-1}} \ge n\log_2(n) - 2,443n + \Omega(\log_2 n) - \frac{\log_2(n!) - n - 1}{2^{n-1}} \ge n\log_2(n) - 2,443n$$

many comparisons are done in the average.

## Quicksort

## The Quicksort-algorithm (Tony Hoare, 1962):

- Choose an array-element p = A[i] (the pivot element).
- Partitioning: Permute the array such that on the left (resp., right) of the pivot element p all elements are  $\leq p$  (resp., > p) (needs n-1 comparisons).
- Apply the algorithm recursively to the subarrays to the left and right of the pivot element.

### Critical: choice of the pivot elements.

- Running time is optimal, if the pivot element is the middle element of the array (median).
- Good choice in practice: median-out-of-three

# **Partitioning**

First, we present a procedure for partitioning a subarray  $A[\ell, ..., r]$  with respect to a pivot element P = A[p], where  $\ell < r$  and  $\ell \le p \le r$ .

The procedure returns an index  $m \in \{\ell, \dots, r\}$  with the following properties:

- A[m] = P
- $A[k] \le P$  for all  $\ell \le k \le m-1$
- A[k] > P for all  $m+1 \le k \le r$

## **Partitioning**

## **Algorithm** Partition

```
function partition(A[\ell \dots r]: array of integer, p: integer): integer
begin
  swap(p, r);
  P := A[r];
  i := \ell - 1:
  for j := \ell to r - 1 do
    if A[j] \leq P then
       i := i + 1:
       swap(i, j)
     endif
  endfor
  swap(i+1,r)
  return i+1
```

endfunction

# **Partitioning**

The following invariants hold before every iteration of the for-loop:

- A[r] = P
- $A[k] \le P$  for all  $\ell \le k \le i$
- A[k] > P for all  $i + 1 \le k \le j 1$

Thus, the following holds before the return-statement:

- $A[k] \le P$  for all  $\ell \le k \le i+1$
- A[k] > P for all  $i + 2 \le k \le r$
- A[i+1] = P

**Note:** partition( $A[\ell \dots r]$ ) makes  $r - \ell$  many comparisons.

## Quicksort

## Algorithm Quicksort

```
procedure quicksort(A[\ell \dots r]: array of integer) begin if \ell < r then p := \text{index of the median of } A[\ell], A[(\ell + r) \text{ div 2}], A[r]; m := \text{partition}(A[\ell \dots r], p); quicksort(A[\ell \dots m - 1]); quicksort(A[m + 1 \dots r]); endif
```

## endprocedure

Worst-case running time:  $\mathcal{O}(n^2)$ .

The worst-case arises when after each call of partition( $A[\ell \dots r]$ , p), one of the subarrays ( $A[\ell \dots m-1]$  or  $A[m+1 \dots r]$ ) is empty.

Average case analysis under the assumption that the pivot element is chosen randomly.

Alternatively: Input array is chosen randomly.

Let Q(n) be the avergage number of comparisons for an input array of length n.

#### Theorem 7

We have Q(n) = 2(n+1)H(n) - 4n, where

$$H(n) := \sum_{k=1}^{n} \frac{1}{k}$$

is the n-th harmonic number.

**Proof:** for n = 1 we have  $Q(1) = 0 = 2 \cdot 2 \cdot 1 - 4 \cdot 1$ .

For n > 2 we have:

$$Q(n) = (n-1) + \frac{1}{n} \sum_{i=1}^{n} [Q(i-1) + Q(n-i)]$$
$$= (n-1) + \frac{2}{n} \sum_{i=1}^{n} Q(i-1)$$

Note:

- (n-1) = number of comparisons for partitioning.
- Q(i-1) + Q(n-i) = average number of comparisons for the recursive sorting of the two subarrays.

The factor 1/n comes from the fact that every pivot element is chosen with probability 1/n.

We get:

$$nQ(n) = n(n-1) + 2\sum_{i=1}^{n} Q(i-1)$$

Hence:

$$nQ(n) - (n-1)Q(n-1) = n(n-1) + 2\sum_{i=1}^{n} Q(i-1)$$
$$-(n-1)(n-2) - 2\sum_{i=1}^{n-1} Q(i-1)$$
$$= n(n-1) - (n-2)(n-1) + 2Q(n-1)$$
$$= 2(n-1) + 2Q(n-1)$$

We obtain:

$$nQ(n) = 2(n-1) + 2Q(n-1) + (n-1)Q(n-1)$$
  
=  $2(n-1) + (n+1)Q(n-1)$ 

Dividing both sides by n(n+1) gives:

$$\frac{Q(n)}{n+1} = \frac{2(n-1)}{n(n+1)} + \frac{Q(n-1)}{n}$$

Using induction on n we get:

$$\frac{Q(n)}{n+1} = \sum_{k=1}^{n} \frac{2(k-1)}{k(k+1)}$$

$$= 2\sum_{k=1}^{n} \frac{(k-1)}{k(k+1)}$$

$$= 2\left(\sum_{k=1}^{n} \frac{k}{k(k+1)} - \sum_{k=1}^{n} \frac{1}{k(k+1)}\right)$$

$$\frac{Q(n)}{n+1} = 2\left[\sum_{k=1}^{n} \frac{1}{k+1} - \sum_{k=1}^{n} \frac{1}{k(k+1)}\right]$$

$$= 2\left[\sum_{k=1}^{n} \frac{2}{k+1} - \sum_{k=1}^{n} \frac{1}{k}\right]$$

$$= 2\left[2\left(\frac{1}{n+1} + H(n) - 1\right) - H(n)\right]$$

$$= 2H(n) + \frac{4}{n+1} - 4.$$

Finally, we get for Q(n):

$$Q(n) = 2(n+1)H(n) + 4 - 4(n+1)$$
  
= 2(n+1)H(n) - 4n.

One has  $H(n) - \ln n \approx 0.57721...$  Euler's constant. Hence:

$$Q(n) \approx 2(n+1)(0.58 + \ln n) - 4n$$
  
  $\approx 2n \ln n - 2.8n \approx 1.38n \log n - 2.8n.$ 

Theoretical optimum:  $\log(n!) \approx n \log n - 1,44n$ ; In the average, quicksort is only 38% worse than the optimum.

An average analysis of the media-out-of-three method yields  $1{,}18n\log n - 2{,}2n$ .

It is in the average only 18% worse than the optimum.

## Heaps

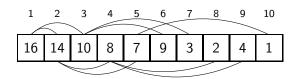

#### Definition 8

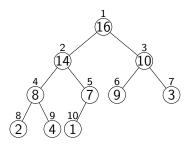

A  $(\max)$ -heap is an array a[1...n] with the following properties:

- $a[i] \ge a[2i]$  for all  $i \ge 1$  with  $2i \le n$
- $a[i] \ge a[2i + 1]$  for all  $i \ge 1$  with  $2i + 1 \le n$

# Heaps

## **Example:**

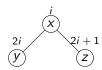

In a first step we will permute the entries of the array a[1, ..., n] such that the heap condition is satisfied.

Assume that the subarray  $a[i+1,\ldots,n]$  already satisfies the heap condition.

In order to enforce the heap condition also for i we let a[i] sink:

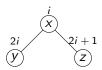

With 2 comparisons one can compute  $\max\{x, y, z\}$ .

In a first step we will permute the entries of the array a[1, ..., n] such that the heap condition is satisfied.

Assume that the subarray  $a[i+1,\ldots,n]$  already satisfies the heap condition.

In order to enforce the heap condition also for i we let a[i] sink:

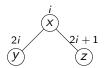

With 2 comparisons one can compute  $\max\{x, y, z\}$ .

If x is the max., then the sinking process stops.

In a first step we will permute the entries of the array a[1, ..., n] such that the heap condition is satisfied.

Assume that the subarray  $a[i+1,\ldots,n]$  already satisfies the heap condition.

In order to enforce the heap condition also for i we let a[i] sink:

With 2 comparisons one can compute  $\max\{x, y, z\}$ .

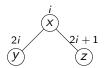

If y is the max., then x and y are swapped and we continue at 2i.

In a first step we will permute the entries of the array a[1, ..., n] such that the heap condition is satisfied.

Assume that the subarray  $a[i+1,\ldots,n]$  already satisfies the heap condition.

In order to enforce the heap condition also for i we let a[i] sink:

With 2 comparisons one can compute  $\max\{x, y, z\}$ .

If z is the max., then x and z are swapped and we continue at 2i + 1.

## Reheap

## **Algorithm** Reheap

```
procedure reheap(i, n: integer)
                                                              (* i \text{ is the root } *)
var m: integer;
begin
  if i < n/2 then
     m := \max\{a[i], a[2i], a[2i+1]\};
                                                              (* 2 comparisons! *)
     if (m \neq a[i]) \land (m = a[2i]) then
       swap(i, 2i);
                                                              (* swap x, y *)
       reheap(2i, n)
     elsif (m \neq a[i]) \land (m = a[2i + 1]) then
       swap(i, 2i + 1);
                                                              (* swap x, z *)
       reheap(2i + 1, n)
     endif
  endif
endprocedure
```

# Building the heap

## Algorithm Build Heap

```
procedure build-heap(n: integer) begin for i := \lfloor \frac{n}{2} \rfloor downto 1 do reheap(i, n) endfor endprocedure
```

**Invariant:** Before the call of reheap(i, n) the subarray a[i + 1, ..., n] satisfies the heap condition.

Clearly, this hods for  $i = \lfloor \frac{n}{2} \rfloor$ .

Assume that the invariant holds for i.

Thus, the heap condition can only fail for i.

After the sinking process for a[i], the heap condition also holds for i.

# Time analysis for building the heap

#### Theorem 9

Built-heap runs in time  $\mathcal{O}(n)$ .

**Proof:** Sinking of a[i] needs  $2 \cdot (\text{height of the subtree under } a[i]) many comparisons.$ 

We carry out the computation for  $n = 2^k - 1$ .

Then we have a complete binary tree of height k-1.

There are

- $2^0$  trees of height k-1,
- $2^1$  trees of height k-2,

:

•  $2^i$  trees of height k-1-i,

:

•  $2^{k-1}$  trees of height 0.

# Time analysis for building the heap

Hence, building the heap needs at most

$$2 \cdot \sum_{i=0}^{k-1} 2^{i} (k-1-i) = 2 \cdot \sum_{i=0}^{k-1} 2^{k-1-i} i$$
$$= 2^{k} \cdot \sum_{i=0}^{k-1} i \cdot 2^{-i}$$
$$\leq (n+1) \cdot \sum_{i>0} i \cdot 2^{-i}$$

many comparisons.

**Claim:** 
$$\sum_{j\geq 0} j \cdot 2^{-j} = 2$$

**Proof of the claim:** For every |z| < 1 we have

$$\sum_{i>0} z^j = \frac{1}{1-z}.$$

# Time analysis for building the heap

Taking derivations yields

$$\sum_{j>0} j \cdot z^{j-1} = \frac{1}{(1-z)^2},$$

and hence

$$\sum_{j>0} j \cdot z^j = \frac{z}{(1-z)^2}.$$

Setting z = 1/2 yields

$$\sum_{i>0} j \cdot 2^{-j} = 2.$$

# Standard Heapsort (W. J. Williams, 1964)

# Algorithm Heapsort procedure heapsort(n: integer)

```
begin

build-heap(n)

for i := n downto 2 do

swap(1, i);

reheap(1, i - 1)

endfor

endprocedure
```

## Theorem 10

Standard Heapsort sorts an array with n elements and needs  $2n \log_2 n + \mathcal{O}(n)$  comparisons.

## Standard Heapsort

#### **Proof:**

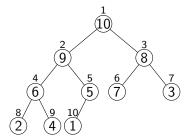

**Correctness:** After build-heap(n), a[1] is the maximal element of the array.

This element will be moved with swap(1, n) to its correct position (n).

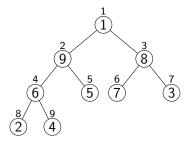

By induction, the subarray  $a[1, \ldots, n-1]$  will be sorted in the remaining steps.

**Running time:** Building the heap needs  $\mathcal{O}(n)$  comparison. Each of the remaining n-1 many reheap-calls needs at most  $2\log_2 n$  comparisons.

#### Bottom-Up Heapsort

**Remark:** An analysis of the average case complexity of Heapsort yields  $2n \log_2 n$  many comparisons in the average. Hence, standard Heapsort cannot compete with Quicksort.

Bottom-up Heapsort needs significantly fewer comparisons.

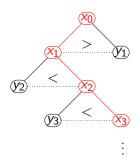

After swap(1, i) one first determines the potential path from the root to a leaf along which the elemente a[i] will sink; the sink path.

For this, one follows the path that always goes to the larger child. This needs at most  $\log n$  instead of  $2\log_2 n$  comparisons.

In most cases, a[i] will sink deep into the heap. It is therefore more efficient to compute the actual position of a[i] on the sink path bottom-up.

The hope is that the bottom-up computations need in total only  $\mathcal{O}(n)$  comparisons.

#### The sink path

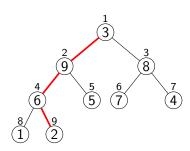

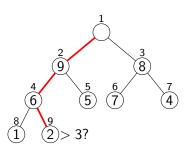

Elements will sink along the path  $[x_0, x_1, x_2, \dots, x_{k-1}, x_k]$  which can be computed with only  $\log_2 n$  comparisons.

We now compute the right position p on the sink path starting from the leaf and going up.

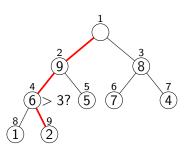

We now compute the right position p on the sink path starting from the leaf and going up.

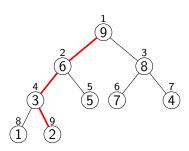

We now compute the right position p on the sink path starting from the leaf and going up.

We now compute the right position p on the sink path starting from the leaf and going up.

We now compute the right position p on the sink path starting from the leaf and going up.

#### Theorem 11

Standard heapsort makes on a portion of at least  $1-2^{-(n-1)}$  many input permutations at least  $2n\log_2(n)-\mathcal{O}(n)$  many comparisons. Bottom-up heapsort makes on a portion of at least  $1-2^{-(n-1)}$  many input permutations at most  $n\log_2(n)+\mathcal{O}(n)$  many comparisons.

**Proof:** information-theoretic argument

A sorting algorithm computes from a permutation of [1, ..., n] the sorted list [1, ..., n].

One can specify (or encode) the input permutation by running the algorithm and in addition output information in form of a  $\{0,1\}$ -string that allows us to run the algorithm backwards starting with the output permutation  $[1,\ldots,n]$ .

In the case of standard heapsort: we output the sink paths, i.e., every time an element is swapped with the left (resp., right) child, we output a 0 (resp., 1). This makes heapsort reversible.

But: We have to know when one sink paths (a  $\{0,1\}$ -string) stops and the next sink path starts.

Alternative 1: We encode a string  $w = a_1 a_2 \cdots a_{t-1} a_t \in \{0,1\}^*$  by

$$c_1(w) = a_1 0 a_2 0 \cdots a_{t-1} 0 a_t 1.$$

Note:  $|c_1(w)| = 2|w|$ .

Alternative 2: We encode a string  $w = a_1 a_2 \cdots a_{t-1} a_t \in \{0,1\}^*$  by

$$c_2(w) = c_1(\text{binary representation of } t)a_1 \cdots a_t$$

Thus,  $|c_2(w)| = |w| + 2\log_2(|w|)$ .

Note:  $c_2(\varepsilon) = 01$ , since 0 = binary representation of the number 0.

We encode the sink path  $w=a_1a_2\cdots a_t\in\{0,1\}^*$  by

$$c_2'(w) = c_1( ext{binary representation of } \log_2(n) - t)a_1 \cdots a_t.$$

Note:  $t \leq \log_2(n)$ , because every sink path has length  $\leq \log_2 n$ .

Our proof showing that building the heap only needs  $\mathcal{O}(n)$  many comparisons also shows: In phase 1, we will output a  $\{0,1\}$ -string of length  $\mathcal{O}(n)$ .

We now analyse the  $\{0,1\}$ -string produced in phase 2.

Let  $t_1, \ldots, t_n$  be the lengths of the sink paths during phase 2.

Hence, we produce in phase 2 a  $\{0,1\}$ -string of length

$$\sum_{i=1}^{n} (t_i + 2 \log_2(\log_2(n) - t_i)) = \sum_{i=1}^{n} t_i + 2 \sum_{i=1}^{n} \log_2(\log_2(n) - t_i).$$

Define the average

$$\bar{t} = \frac{\sum_{i=1}^{n} t_i}{n}.$$

The function f with  $f(x) = \log_2(\log_2(n) - x)$  is concave on  $(-\infty, \log_2(n))$ . Jensen's inequality (slide 4) implies:

$$\log_2(\log_2(n) - \overline{t}) \geq \sum_{i=1}^n \frac{1}{n} \cdot \log_2(\log_2(n) - t_i)).$$

Therefore:

$$\sum_{i=1}^{n} t_i + 2 \sum_{i=1}^{n} \log_2(\log_2(n) - t_i)) \leq n\bar{t} + 2n \log_2(\log_2(n) - \bar{t}).$$

To sum up: The input permutation  $\sigma$  on  $[1,\ldots,n]$  can be encoded by a  $\{0,1\}$ -string of length

$$I(\sigma) \le cn + n\bar{t} + 2n\log_2(\log_2(n) - \bar{t}),$$

where c is a constant (for phase 1).

Lemma 6 implies

$$cn + n\overline{t} + 2n\log_2(\log_2(n) - \overline{t}) \ge I(\sigma) \ge \log_2(n!) - n \ge n\log_2(n) - 2,443n$$

for at least  $(1-2^{-n+1})n!$  many input permutations.

With d = 2,443 + c we get:

$$\bar{t} \ge \log_2(n) - 2\log_2(\log_2(n) - \bar{t}) - d. \tag{1}$$

Since  $\bar{t} \geq 0$  we obtain

$$\bar{t} \ge \log_2(n) - 2\log_2(\log_2(n)) - d. \tag{2}$$

From (1) and (2) we get the better estimate

$$\bar{t} \ge \log_2(n) - 2\log_2(2\log_2(\log_2(n)) + d) - d.$$
 (3)

This estimate can be again applied to (1), and so on.

In general, we get for all  $i \geq 1$ :

$$\bar{t} \ge \log_2(n) - \alpha_i - d$$

where  $\alpha_1 = 2 \log_2(\log_2(n))$  and  $\alpha_{i+1} = 2 \log_2(\alpha_i + d)$ . (proof by induction on  $i \ge 1$ )

For all  $x \ge \max\{10, d\}$  we have:

$$2\log_2(x+d) \le 2\log_2(2x) = 2\log_2(x) + 2 \le 0, 9 \cdot x.$$

Hence, as long as  $\alpha_i \ge \max\{10, d\}$  holds, we have  $\alpha_{i+1} \le 0, 9 \cdot \alpha_i$ .

Therefore, there exists a constant  $\alpha$  with

$$\bar{t} \ge \log_2(n) - \alpha - d.$$
 (4)

Thus, for at least  $(1-2^{-n+1})n!$  many input permutations we have

$$\sum_{i=1}^n t_i \ge n \log_2 n - \mathcal{O}(n).$$

The statement of Theorem 11 for standard Heapsort follows easily:

In phase 2, standard Heapsort makes  $2\sum_{i=1}^{n} t_i$  many comparisons.

Hence, standard-Heapsort makes for at least  $(1-2^{-n+1})n!$  many input permutations at least  $2n\log_2 n - \mathcal{O}(n)$  many comparisons.

Bottom-up heapsort makes in phase 2 at most

$$n\log_2(n) + \sum_{i=1}^n (\log_2(n) - t_i) = 2n\log_2(n) - \sum_{i=1}^n t_i$$

many comparisons.

Hence, bottom-up Heapsort makes for at least  $(1-2^{-n+1})n!$  many input permutations at most

$$\mathcal{O}(n) + 2n\log_2(n) - \sum_{i=1}^n t_i \le n\log_2(n) + \mathcal{O}(n)$$

many comparisons.

## Variant by Svante Carlsson, 1986

One can show that bottom-up Heapsort makes in the worst case at most  $1.5n \log n + \mathcal{O}(n)$  many comparisons.

Carlsson proposed to determine the correct position on the sink path using binary search.

This yields a worst-case bound of  $n \log n + \mathcal{O}(n \log \log n)$  many comparison.

On the other hand, in practice binary search on the sink path does not seem to pay off.

#### Counting-Sort

Recall: The lower bound of  $\Omega(n \log n)$  only holds for comparison-based sorting algorithms.

If we make further assumptions on the array elements, we can sort in time  $\mathcal{O}(n)$ .

**Assumption:** The array elements  $A[1], \ldots, A[n]$  are natural numbers in the range [0, k].

Counting sort (see next slide) sorts under this assumption in time  $\mathcal{O}(k+n)$ .

Hence, if  $k \in \mathcal{O}(n)$ , then counting sort works in linear time.

## Counting Sort

#### **Algorithm** Counting-Sort

```
procedure counting-sort(array A[1, n] with A[1], \dots A[n] \in [0, k])
begin
  var Arrays C[0, k], B[1, n]
  for i := 0 to k do
    C[i] := 0
  for i := 1 to n do
    C[A[i]] := C[A[i]] + 1
  for i := 1 to k do
    C[i] := C[i] + C[i-1]
  for n downto 1 do
    B[C[A[i]]] := A[i]:
    C[A[i]] := C[A[i]] - 1
endprocedure
```

### Counting Sort

After the first three for-loops, C[i] is the number of array entries that are  $\leq i$ .

The statement B[C[A[i]]] := A[i] puts the array element A[i] at the right position C[A[i]].

**Remark:** Counting sort is a stable sorting algorithm.

This means: If A[i] = A[j] for i < j, then in the sorted array B the array entry A[i] is to the left of A[j].

This is relevant if the array entries consist of (i) keys that are used for sorting and (ii) additional informations.

Stability of counting sort will be needed for radix sort on the next slide.

#### Radix Sort

We use counting sort to sort an array A[1, n], where  $A[1], \ldots, A[n]$  are d-ary numbers in base k (where the least significant digit is the left most digit).

Radix sort sorts such an array in time O(d(n+k)).

If in addition  $d \in \mathcal{O}(1)$  and  $k \in \mathcal{O}(n)$  (which means that we can represent number of size  $\mathcal{O}(n^d)$ ), then radix sort works in linear time.

#### Algorithm Radix Sort

```
procedure radix sort(array A[1, n] with A[1], \ldots A[n]) begin for i := 1 to d do sort the array A with counting sort with respect to the i-th digit. endfor
```

endprocedure

#### Computation of the Media

Input: array a[1, ..., n] of numbers and  $1 \le k \le n$ .

Output: k-th smallest element, i.e., the number  $m \in \{a[i] \mid 1 \le i \le n\}$  such that

$$|\{i \mid a[i] < m\}| \le k - 1$$
 and  $|\{i \mid a[i] > m\}| \le n - k$ 

Special case:  $k = \lceil n/2 \rceil \rightsquigarrow \text{median}$ 

Naive approach:

- sort the array a in time  $\mathcal{O}(n \log n)$ ,
- output the k-th element of the sorted array.

#### Median of the medians

Goal: Compute the *k*-th smallest element in linear time.

Idea: Compute a pivot element (as in quick sort) as the median of the medians of blocks of length 5.

- We split the array in blocks of length 5.
- For each block we compute the median (6 comparisons are sufficient).
- Compute recursively the median p of the array of medians and take p
  as the pivot element.

Number of comparisons:  $T(\frac{n}{5})$ .

# Quick sort step

Partition the array with the pivot element p such that for suitable positions  $m_1 < m_2$  we have:

$$a[i] < p$$
 for  $1 \le i \le m_1$   
 $a[i] = p$  for  $m_1 < i \le m_2$   
 $a[i] > p$  für  $m_2 < i \le n$ 

Number of comparisons:  $\leq n$ .

#### Case distinction:

- **1**  $k \leq m_1$ : Search for the k-th element recursively in  $a[1], \ldots, a[m_1]$ .
- $m_1 < k \le m_2$ : Return p.
- 3  $k > m_2$ : Search for the  $(k m_2)$ -th element in  $a[m_2 + 1], \ldots, a[n]$ .

### 30 – 70 splitting

The choice of the pivot element as the median of the medians (of blocks of length 5) ensures the following inequalities for  $m_1, m_2$ :

$$\frac{3}{10}n \le m_2 \qquad \text{and} \qquad m_1 \le \frac{7}{10}n$$

Therefore, the recursive step needs at most  $T(\frac{7n}{10})$  comparisons.

#### Total time

T(n) is the total number of comparisons comparisons for an array of length n.

We get the following recurrence for T(n):

$$T(n) \leq T\left(\lceil \frac{n}{5} \rceil\right) + T\left(\lceil \frac{7n}{10} \rceil\right) + \mathcal{O}(n)$$

The master theorem II gives  $T(n) \in \mathcal{O}(n)$ .

# More precise analysis

$$T(n) = T\left(\frac{n}{5}\right) + T\left(\frac{7n}{10}\right) + \frac{6n}{5} + \frac{2n}{5},$$

where:

- $\frac{6n}{5}$  is the number of comparisons to compute the medians of the blocks of length 5.
- $\frac{2n}{5}$  is the number of comparisons for the partitioning step.

This yields the bound  $T(n) \leq 16n$ :

With 
$$\frac{1}{5} + \frac{7}{10} = \frac{9}{10}$$
 we get  $T(n) \le T(\frac{9n}{10}) + \frac{8n}{5}$  and hence  $T(n) \le 10 \cdot \frac{8n}{5} = 16n$ .

#### Quick select

Quick select is a randomized algorithm for computing the median:

#### **Algorithm**

```
function quickselect(A[\ell \dots r]: array of integer, k: integer): integer
begin
  if \ell = r then return A[\ell]
  else
     p := \text{random}(\ell, r);
     m := partition(A[\ell \dots r], p);
     k' := (m - \ell + 1):
     if k = k' then return A[m]
     elsif k < k' then return quickselect(A[\ell \dots m-1], k)
     else return quickselect(A[m+1...r], k-k')
     endif
  endif
```

#### endfunction

### Analysis of quick select

Let Q(n) be the average number of comparisons that quick select is doing for an array with n elements.

We have:

$$Q(n) \le (n-1) + \frac{1}{n} \sum_{i=1}^{n} Q(\max\{i-1, n-i\}),$$

where:

- ullet (n-1) is the number of comparisons for partitioning the array, and
- $Q(\max\{i-1, n-i\})$  is the (maximal) average number of comparisons for a recursive call on *one* of the two subarrays.

Here, we make the pessimistic assumption that we continue searching in the larger subarray.

# Analysis of quick select

We have

$$Q(n) \leq (n-1) + \frac{1}{n} \sum_{i=1}^{n} Q(\max\{i-1, n-i\})$$

$$= (n-1) + \frac{1}{n} \left( \sum_{i=\lceil \frac{n}{2} \rceil}^{n-1} Q(i) + \sum_{i=\lfloor \frac{n}{2} \rfloor}^{n-1} Q(i) \right)$$

Claim:  $Q(n) \leq 4 \cdot n$ :

Proof by induction on n: OK for n = 1.

Let  $n \ge 2$  and let  $Q(i) \le 4 \cdot i$  for all i < n.

# Analysis of quick select

Case 1: *n* is even.

$$Q(n) \leq (n-1) + \frac{2}{n} \sum_{i=\frac{n}{2}}^{n-1} Q(i)$$

$$\leq (n-1) + \frac{8}{n} \sum_{i=\frac{n}{2}}^{n-1} i$$

$$= (n-1) + \frac{8}{n} \left( \frac{(n-1)n}{2} - \frac{(\frac{n}{2}-1)\frac{n}{2}}{2} \right)$$

$$= (n-1) + 4(n-1) - n + 2$$

$$= 4n - 3 \leq 4n$$

### Analyse von Quickselect

Case 2: n is odd.

$$Q(n) \leq (n-1) + \frac{2}{n} \sum_{i=\lceil \frac{n}{2} \rceil}^{n-1} Q(i) + \frac{1}{n} Q\left(\left\lfloor \frac{n}{2} \right\rfloor\right)$$

$$\leq (n-1) + \frac{8}{n} \sum_{i=\lceil \frac{n}{2} \rceil}^{n-1} i + 2$$

$$= (n-1) + \frac{8}{n} \cdot \left(\frac{(n-1)n}{2} - \frac{(\lceil \frac{n}{2} \rceil - 1) \lceil \frac{n}{2} \rceil}{2}\right) + 2$$

$$\leq (n-1) + 4(n-1) - n - 2 + 2$$

$$= 4n - 5 \leq 4 \cdot n.$$

#### Overview

- Matroids
- Kruskal's algorithm for spanning trees
- Dijkstra's algorithm for shortest paths

## Greedy algorithms

Algorithms that take in each step the locally best optimal choice are called greedy.

For some problems this yields a globally optimal solution.

Problems where greedy algorithms always find an optimal solution can be characterized via the notion of a matroid.

## Optimization problems

Let E be a finite set and  $U \subseteq 2^E$  a set of subsets of E.

A pair (E, U) is a subset system, if the following holds:

- ∅ ∈ U
- If  $A \subseteq B \in U$  then  $A \in U$  as well.

A set  $A \in U$  is maximal (with respect to  $\subseteq$ ) if for all  $B \in U$  the following holds: if  $A \subseteq B$ , then A = B.

The optimization problems associated with (E, U) is:

- Input: A weight function  $w: E \to \mathbb{R}$
- Output: A maximal set  $A \in U$  with  $w(A) \ge w(B)$  for all maximal sets  $B \in U$ , where

$$w(C) = \sum_{a \in C} w(a)$$

We call A an optimal solution.

# Optimization problems

In order to solve such optimization problems, one can try to use the following generic greedy algorithm:

#### Algorithm generic greedy algorithm

```
procedure find-optimal (subset system (E,U), w:E\to\mathbb{R}) begin order set E by descending weights as e_1,e_2,\ldots,e_n with w(e_1)\geq w(e_2)\geq \cdots \geq w(e_n) T:=\emptyset for k:=1 to n do if T\cup\{e_k\}\in U then T:=T\cup\{e_k\} endfor return (T) endprocedure
```

**Note:** The solution computed by the generic greedy algorithm is always a maximal subset.

Unfortunately there exist subset systems for which the generic greedy algorithm does not find an optimal solution (will be shown later).

A subset system (E, U) is a matroid, if the following property (exchange property) holds:

$$\forall A, B \in U : |A| < |B| \implies \exists x \in B \setminus A : A \cup \{x\} \in U$$

**Remark:** If (E, U) is a matroid, then all maximal sets in U have the same cardinality.

**Example:** Let *E* be a finite set and  $k \leq |E|$ . Then

$$(E, \{A \subseteq E \mid |A| \le k\})$$

is a matroid.

#### Theorem 12

Let (E,U) be a subset system. The generic greedy algorithm computes for every weight function  $w:E\to\mathbb{R}$  an optimal solution if and only if (E,U) is a matroid.

**Proof:** First assume that (E, U) is a matroid.

Let  $w: E \to \mathbb{R}$  be a weight function and let  $E = \{e_1, e_2, \dots, e_n\}$  with

$$w(e_1) \geq w(e_2) \geq \cdots \geq w(e_n).$$

Let  $T = \{e_{i_1}, \dots, e_{i_k}\}$  with  $i_1 < i_2 < \dots < i_k$  the solution computed by the generic greedy algorithm.

Assumption: There exists a maximal set  $S = \{e_{j_1}, \dots, e_{j_l}\} \in U$  with w(S) > w(T), where  $j_1 < j_2 < \dots < j_l$ .

Since (E, U) is a matroid, we have k = I.

Since w(S) > w(T), there exists  $1 \le p \le k$  with  $w(e_{j_p}) > w(e_{i_p})$ .

Since the weights where sorted in descending order, we must have  $j_p < i_p$ .

We now apply the exchange property to the sets

$$A=\{e_{i_1},\ldots,e_{i_{p-1}}\}\in U$$
 and  $B=\{e_{j_1},\ldots,e_{j_p}\}\in U.$ 

Since |A| < |B|, there exists an element  $e_{j_a} \in B \setminus A$  with  $A \cup \{e_{j_a}\} \in U$ .

We get  $j_a \leq j_p < i_p$ .

But then, the generic greedy algorithm would have put  $e_{ia}$  into the solution, which is a contradiction.

Now assume that (E, U) is not a matroid, i.e., the exchange property does not hold.

Let  $A, B \in U$  with |A| < |B| such that for all  $b \in B \setminus A$ :  $A \cup \{b\} \notin U$ .

Let r = |B| and hence  $|A| \le r - 1$ .

Define the weight function  $w : E \to \mathbb{R}$  as follows:

$$w(x) = egin{cases} r+1 & ext{for } x \in A \\ r & ext{for } x \in B \setminus A \\ 0 & ext{otherwise} \end{cases}$$

The generic greedy algorithm must compute a solution T with  $A \subseteq T$  and  $T \cap (B \setminus A) = \emptyset$ .

We get 
$$w(T) = (r+1) \cdot |A| \le (r+1)(r-1) = r^2 - 1$$
.

Let  $S \in U$  be a maximal subset with  $B \subseteq S$ .

We get 
$$w(S) \ge w(B) \ge r^2$$
.

### Spanning subtrees

Let G = (V, E) be a finite undirected graph.

A path from  $u \in V$  to  $v \in V$  is a sequence of nodes  $(u_1, u_2, \dots, u_n)$  with  $u_1 = u$ ,  $u_n = v$  and  $(u_i, u_{i+1}) \in E$  for all  $1 \le i \le n-1$ .

*G* is connected, if for all  $u, v \in V$  with  $u \neq v$  there exists a path from u to v.

A circuit is a path  $(u_1, u_2, \dots, u_n)$  with  $n \ge 3$ ,  $u_i \ne u_j$  for all  $1 \le i < j \le n$  and  $(u_n, u_1) \in E$ .

*G* is a tree, if it is connected and has no circuits.

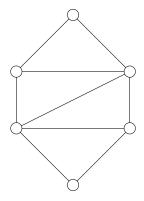

**Excercise**: for every tree T = (V, E) we have |E| = |V| - 1.

Let G = (V, E) be connected. A spanning subtree of G is a subset  $F \subseteq E$  of edges such that (V, F) is a tree.

**Excercise**: every connected graph has a spanning subtree.

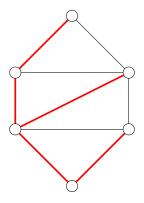

# Spanning subtrees

#### **Example:**

# Spanning subtrees

#### **Example:**

## Matroid of circuit-free edge sets

Let G = (V, E) be again connected, and let  $w : E \to \mathbb{R}$  be a weight function.

The weight of a spanning subtree  $F \subseteq E$  is

$$w(F) = \sum_{e \in F} w(e).$$

Goal: Compute a spanning subtree of maximal weight.

The following lemma allows us to use the canonical greedy algorithm:

#### Lemma 13

The subset system  $(E, \{A \subseteq E \mid (V, A) \text{ has no circuit}\})$  is a matroid.

## Matroid of circuit-free edge sets

**Proof:** Let  $A, B \subseteq E$  be edge sets without circuits such that |A| < |B|.

Let  $V_1, V_2, \dots, V_n$  be the connected components of the (V, A).

We have  $|A| = \sum_{i=1}^{n} (|V_i| - 1)$ , because the subtree of (V, A) induced by  $V_i$  is a tree and therefore has  $|V_i| - 1$  many edges.

For every edge  $e = (u, v) \in B$  one of the following two cases holds:

- There is  $1 \le i \le n$  with  $u, v \in V_i$ .
- ② There are  $i \neq j$  with  $u \in V_i$  and  $v \in V_j$ .

But in B there can exist at most  $\sum_{i=1}^{n}(|V_i|-1)=|A|$  many edges of type 1 (otherwise B would contain a circuit in one of the sets  $V_i$ ).

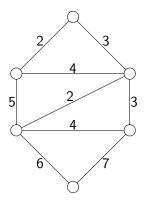

Hence, there exists an edge  $e \in B$ , which connects two connected components of (V, A).

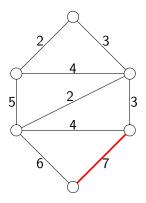

Thus,  $A \cup \{e\}$  contains no circuit.

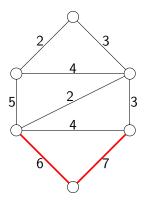

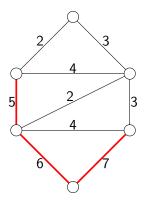

#### Algorithm Kruskals algorithm

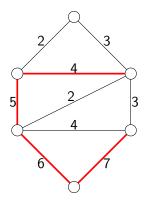

```
procedure kruskal (edge-weighted connected graph (V, E, w))
begin
  sort E by decreasing weights e_1, e_2, \ldots, e_n with
  w(e_1) \geq w(e_2) \geq \cdots \geq w(e_n)
  F := \emptyset
  for k := 1 to n do
     if e_k connects two different connected components of (V, F) then
       F := F \cup \{e_k\}
  endfor
  return (F)
endprocedure
```

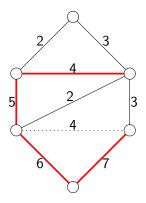

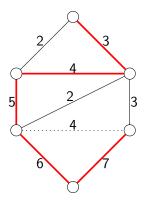

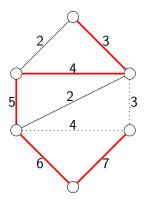

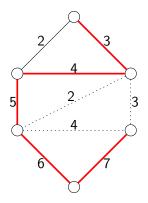

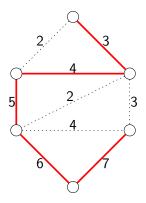

## Running time of Kruskal's algorithm

**Note:** Since *G* is connected, we have  $|V| - 1 \le |E| \le |V|^2$ .

Sorting the edges by weight needs time  $\mathcal{O}(|E|\log|E|) = \mathcal{O}(|E|\log|V|)$ .

The connected components of (V, F) can be maintained by a partition of the node set V.

We start with the partition  $\{\{v\} \mid v \in V\}$ .

In every iteration of the **for**-loop (|E| many) we test whether the end points of the edge  $e_k$  belong to different sets A, B of the partition.

If this holds, then we replace in the partition the sets A and B by the set  $A \cup B$ .

For this, we will later develop a so-called union-find data structure, which realizes the above operations in total time  $\mathcal{O}(\alpha(|V|)\cdot|E|)$  for an extremely slow-growing function  $\alpha$ .

This gives the running time  $\mathcal{O}(|E| \log |V|)$  for Kruskal's algorithm.

### Shortest paths

Another example for a greedy strategy: Computation of shortest paths in an edge-weighted directed graph  $G = (V, E, \gamma)$ .

- V is the set of nodes
- $E \subseteq V \times V$  is the set of edges, where  $(x, x) \notin E$  for all  $x \in V$ .
- $\gamma: E \to \mathbb{N}$  is the weight function.

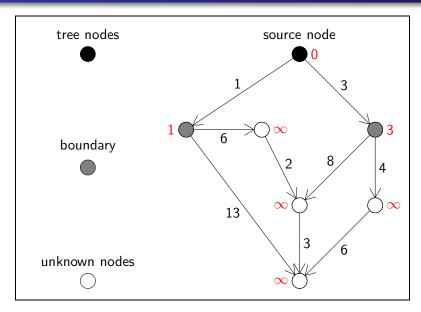

Weight of a path 
$$(v_0, v_1, v_2, ..., v_n)$$
:  $\sum_{i=0}^{n-1} \gamma(v_i, v_{i+1})$ 

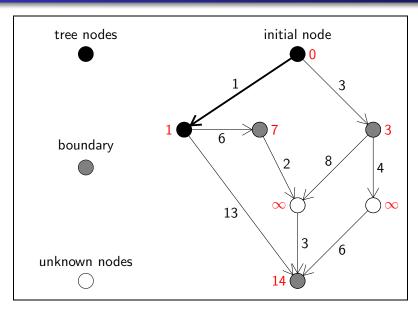

For  $u, v \in V$ , d(u, v) denotes the minimum of the weight of all paths from u to v ( $d(u, v) = \infty$  if such a path does not exist, and d(u, u) = 0).

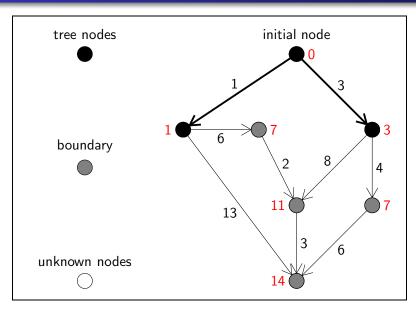

**Goal:** Given  $G = (V, E, \gamma)$  and a source node  $u \in V$ , compute for every  $v \in V$  a path  $u = v_0, v_1, v_2, \ldots, v_{n-1}, v_n = v$  with minimal weight d(u, v).

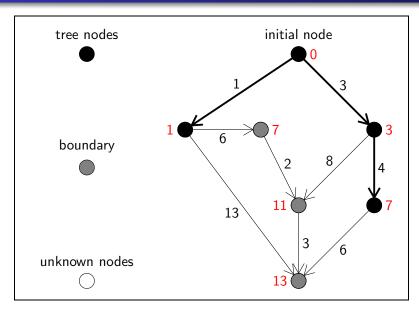

### Dijkstra's algorithm

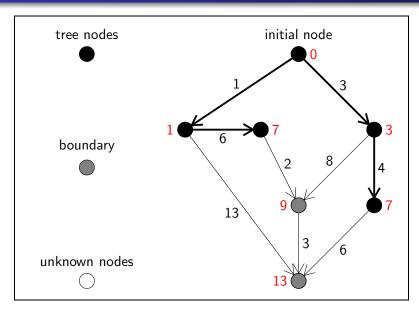

```
B := \emptyset (tree nodes); R := \{u\} (boundary); U := V \setminus \{u\} (unknown nodes);
p(u) := nil; D(u) := 0;
while R \neq \emptyset do
  x := \mathbf{nil}: \alpha := \infty:
  forall y \in R do
     if D(y) < \alpha then
        x := y; \alpha := D(y)
     endif
  endfor
   B := B \cup \{x\}; R := R \setminus \{x\}
  forall (x, y) \in E do
     if y \in U then
        D(y) := D(x) + \gamma(x, y); p(y) := x; U := U \setminus \{y\}; R := R \cup \{y\}
     elsif y \in R and D(x) + \gamma(x, y) < D(y) then
        D(y) := D(x) + \gamma(x, y); p(y) := x
     endif
  endfor
endwhile
```

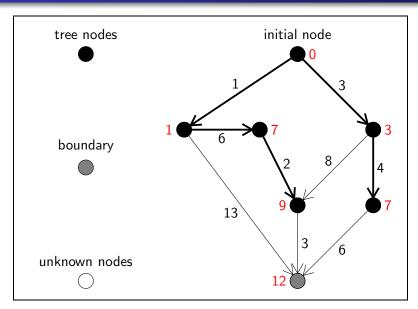

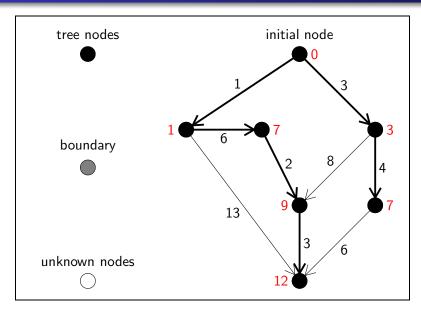

#### Theorem 14 (Correctness of Dijkstra's algorithm)

Dijkstra's algorithm computes shortest paths from the source node to all other nodes.

**Proof:** We show that the following invariants are preserved by the loop-body of the **while**-loop:

- The sets B, R, and U form a partition of the node set V.
- ②  $R = \{y \mid \exists x \in B : (x, y) \in E\} \setminus B$
- **③** for all  $y \in R$ ,  $D(y) = \min\{D(x) + \gamma(x, y) \mid x \in B, (x, y) \in E\}$

Consider an execution of the body of the **while**-Schleife, where the node x is moved from R to B.

(1)–(4) hold before the execution of the loop-body.

It is clear that (1) and (2) are preserved.

(3): Because of (3) and (4) there exists a node  $z \in B$  with

$$D(x) = D(z) + \gamma(z, x) = d(u, z) + \gamma(z, x).$$

Hence, there is path from u to x with weight D(x).

Assume that there is a path from u to x with weight < D(x).

Let  $w \in R$  be the first node on this path, which does not belong to B (must exist since  $x \notin B$ ) and let  $v \in B$  be the predecessor of w on the path (exists, since  $u \in B$ ).

Since the whole path has weight < D(x), we get

$$D(w) = \min\{D(w') + \gamma(w', w) \mid w' \in B, (w', w) \in E\}$$

$$\leq D(v) + \gamma(v, w) < D(x),$$

which contradicts the choice of  $x \in R$ .

Hence, we must have d(u, x) = D(x).

(4): Let B', R', U', D' be the values of the variables B, R, U, D after the execution of the loop-body.

Note:  $B' = B \cup \{x\}$ , D(z) = D'(z) for all  $z \in B$  and D(x) = D'(x). Let  $y \in R'$ .

Case 1:  $y \in R \setminus \{x\}$  and  $(x, y) \in E$ . We have

$$D'(y) = \min\{D(y), D(x) + \gamma(x, y)\}$$

$$= \min\{\min\{D(z) + \gamma(z, y) \mid z \in B, (z, y) \in E\}, D(x) + \gamma(x, y)\}$$

$$= \min\{\min\{D'(z) + \gamma(z, y) \mid z \in B, (z, y) \in E\}, D'(x) + \gamma(x, y)\}$$

$$= \min\{D'(z) + \gamma(z, y) \mid z \in B', (z, y) \in E\}$$

Case 2:  $y \in R \setminus \{x\}$  and  $(x, y) \notin E$ . We have

$$D'(y) = D(y)$$
= min{D(z) + \gamma(z,y) | z \in B, (z,y) \in E}
= min{D'(z) + \gamma(z,y) | z \in B', (z,y) \in E}.

Case 3:  $y \notin R$ . We have  $(x, y) \in E$ , but there is no edge  $(z, y) \in E$  with  $z \in B$  (by (2)).

Hence, we have

$$D'(y) = D(x) + \gamma(x, y)$$
  
=  $D'(x) + \gamma(y, x)$   
=  $\min\{D'(z) + \gamma(z, y) \mid z \in B', (z, y) \in E\}.$ 

Remark: Dijkstra's algorithm in general does not produce a correct result if negative edge weights are allowed.

WS 2016/2017

# Dijkstra with abstract data types for the boundary

In order to analyze the running time of Dijkstra's algorithm, it is uselful to reformulate the algorithm with an abstract data type for the boundary R.

The following operations are needed for the boundary R:

**insert** insert a new element into R.

**decrease-key** decrease the key value of an element of R.

**delete-min** find the element from R with the smallest key value

and remove it from R.

# Dijkstra with abstract data types for the boundary

```
B := \emptyset; R := \{u\}; U := V \setminus \{u\}; p(u) := nil; D(u) := 0;
while (R \neq \emptyset) do
  x := delete-min(R);
  B := B \cup \{x\};
  forall (x, y) \in E do
     if v \in U then
        U := U \setminus \{y\}; \ p(y) := x; \ D(y) := D(x) + \gamma(x, y);
        insert(R, v, D(v)):
     elsif y \in R and D(x) + \gamma(x, y) < D(y) then
        p(y) := x; D(y) := D(x) + \gamma(x, y);
        decrease-key(R, v, D(v)):
     endif
  endfor
endwhile
```

# Running time of Dijkstra's algorithm

Number of operations (n = number of nodes, e = number of edges):

```
insert n
decrease-key e
delete-min n
```

The total running time depends of the data structure that is used for the boundary:

- Array of size n: single insert/decrease-key:  $\mathcal{O}(1)$ single delete-min:  $\mathcal{O}(n)$ total running time:  $\mathcal{O}(n+e+n^2)=\mathcal{O}(n^2)$
- ② Heap (balanced binary tree of depth  $\mathcal{O}(\log(n))$ : single insert/decrease-key/delete-min:  $\mathcal{O}(\log(n))$  total running time:  $\mathcal{O}(n\log(n) + e\log(n)) = \mathcal{O}(e\log(n))$ . If  $\mathcal{O}(e) \subseteq o(n^2/\log n)$ , then the heap beats the array. For instance, for planar graphs one has e < 3n 6 for n > 3.

# Fibonacci heaps (Fredman & Tarjan 1984)

Fibonacci heaps beat arrays as well as heaps:  $O(e + n \log n)$ 

Ein Fibonacci heap H is a list of rooted trees, i.e., a forest.

V is the set of nodes

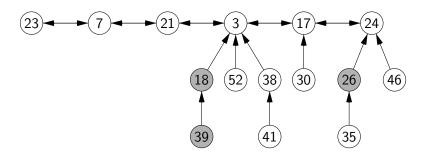

Every node  $v \in V$  has a key  $key(v) \in \mathbb{N}$ .

Heap condition:  $\forall x \in V : y \text{ is a child of } x \Rightarrow key(x) \leq key(y)$ 

Some of nodes of V are marked. The root of a tree is never marked.

### Example for a Fibonacci heap

(key values are in the circles, marked nodes are grey)

### Fibonacci heaps

- The parent-child relation has to be realized by pointers, since the trees in a Fibonacci heap are not necessarily balanced.
- That means that pointer manipulations (expensive!) replace the index manipulations (cheap!) in standard heaps.
- Operations:
  - merge
  - insert
  - delete-min
  - decrease-key

### Implementation of merge and insert

- merge: Concatenation of two lists constant time
- insert: Special case of merge constant time
- merge and insert produce long lists of one-element trees.
- Every such list is a Fibonacci heap.

### Implementation of delete-min

- Let H be a Fibonacci heap consisting of T trees and n nodes.
- for a nodes  $x \in V$  let rank(x) be the number of children of x.
- for a tree B in H let rank(B) be the rank of the root of B.
- Let  $r_{\text{max}}(n)$  be the maximal rank that can appear in a Fibonacci heap with n nodes.
- Clearly,  $r_{max}(n) \le n$ . Later, we will show that  $r_{max}(n) \in \mathcal{O}(\log n)$ .

### Implementation of delete-min

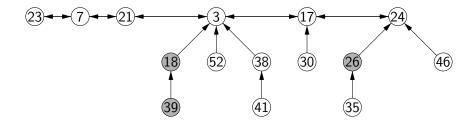

- **1** Search for the root x with minimal key. Time:  $\mathcal{O}(T)$
- 2 Remove x and replace the subtree rooted in x by its rank(x) many subtrees. Remove possible markings from the new roots. Time:  $\mathcal{O}(\operatorname{rank}(x)) \subseteq \mathcal{O}(r_{\max}(n))$ .
- **3** Define an array  $L[0, ..., r_{max}(n)]$ , where L[i] is a list of all trees of rank i.

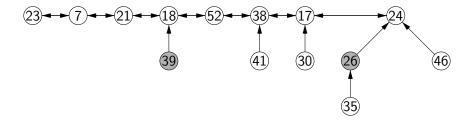

Time:  $\mathcal{O}(T + r_{\mathsf{max}}(n))$ .

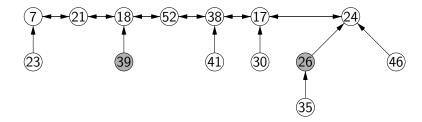

**o** for i := 0 to  $r_{max}(n) - 1$  do while |L[i]| > 2 do remove two trees from L[i]make the root with the larger key to a child of the other root add the resulting tree to L[i+1]

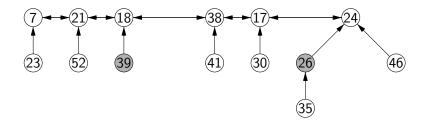

endwhile endfor

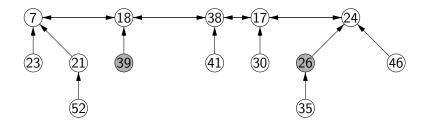

Time:  $\mathcal{O}(T + r_{\mathsf{max}}(n))$ 

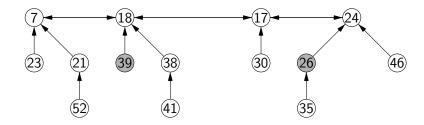

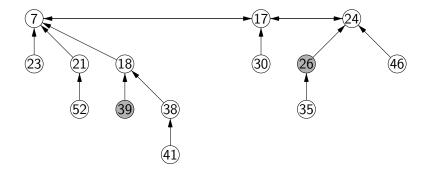

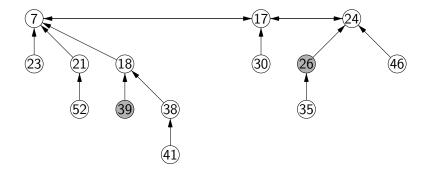

#### Remarks for delete-min

- **delete-min** needs time  $\mathcal{O}(T + r_{\text{max}}(n))$ , where T is the number of trees before the operation.
- After the execution **delete-min**, there exists for every  $i \le r_{\text{max}}(n)$  at most one tree of rank i.
- Hence, the number of trees after **delete-min** is bounded by  $r_{max}(n)$ .

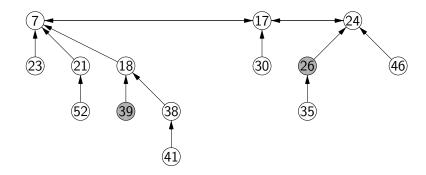

### Implementation of decrease-key

Let *x* be the node for which the key is reduced.

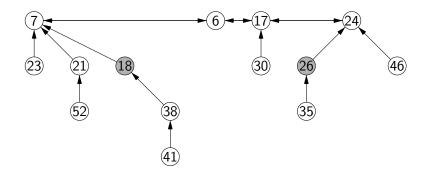

- ① If x is a root, then we can reduced key(x) without any other modifications.
  - Now assume that x is not a root and let  $x = y_0, y_1, \ldots, y_m$  be the path from x to the root  $y_m$  ( $m \ge 1$ ).
  - Let  $y_k$   $(1 \le k \le m)$  be the first node on this path, which is not x and which is not marked (note:  $y_m$  is not marked).
- ② For all  $0 \le i < k$ , we cut off  $y_i$  from its parent node  $y_{i+1}$  and remove the marking from  $y_i$  ( $y_0 = x$  can be marked).  $y_i$  ( $0 \le i < k$ ) is now a unmarked root of a new tree.
- **3** If  $y_k$  is not a root, then we mark  $y_k$  (this tells us later that  $y_k$  lost a child).

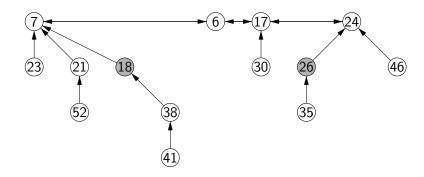

decrease-key(node with key 39,6)

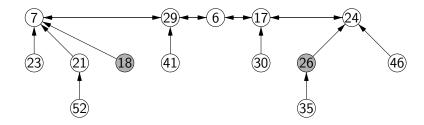

decrease-key(node with key 39,6)

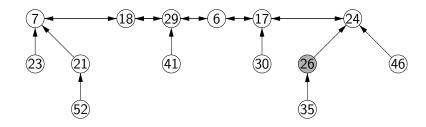

decrease-key(node with key 38, 29)

decrease-key(node with key 38, 29)

decrease-key(node with key 38, 29)

### Remarks for decrease-key

- Time:  $\mathcal{O}(k) + \mathcal{O}(1)$
- **decrease-key** reduces the number of marked nodes by at least k-2 ( $k \ge 1$ ).
- **decrease-key** increases the number of trees by *k*.

### Definition of Fibonacci heaps

#### Definition 15

A Fibonacci heap is eine list of rooted trees as described before, which can be obtained from the empty list be an arbitrary sequence of **merge**, **insert**, **delete-min**, and **decrease-key** operations

#### Lemma 16 (Fibonacci heap lemma)

Let x be a node of a Fibonacci heap with rank(x) = k.

- If  $c_1, \ldots, c_k$  are the children of x, and  $c_i$  became a child of x before  $c_{i+1}$  became a child of x, then  $rank(c_i) \ge i 2$ .
- ② The subtree rooted in x contains at least  $F_{k+1}$  many nodes. Here,  $F_{k+1}$  is the (k+1)-th Fibonacci number  $(F_0 = F_1 = 1, F_{k+1} = F_k + F_{k-1} \text{ for } k \ge 1)$ .

### Proof of the Fibonacci heap lemma

#### Part 1:

At the time instant t, where  $c_i$  became a child of x, the nodes  $c_1, \ldots, c_{i-1}$  were already children of x, i.e., the rank of x at time t was at least i-1.

Since only trees with equal rank are merged to a single tree (in **delete-min**), that rank of  $c_i$  at time t was at least i-1 as well.

In the meantime (i.e. after time t),  $c_i$  can loose at most one child: If  $c_i$  looses one child due to a **decrease-key**, then  $c_i$  will be marked, and after loosing second child,  $c_i$  will be cut off from the parent node x.

Hence,  $rank(c_i) \ge i - 2$ .

### Proof of the Fibonacci heap lemma

#### Part 2:

Proof by induction on the height of the subtree rooted at x.

If x is a leaf, then k = 0 and the subtree rooted in x contains  $1 = F_1$  node.

If x is not a leaf then we can count the number of nodes in the subtree rooted at x as follows:

- $\bigcirc$  2 (for x and  $c_1$ ) plus
- ② the number of nodes in the subtree rooted at  $c_i$  (for  $2 \le i \le k$ ), which has rank  $c_{i-2}$  (by part 1) and therefore contains by induction at least  $F_{i-1}$  many nodes.

Hence the subtree rooted in x contains at least

$$2 + \sum_{i=2}^{k} F_{i-1} = 2 + \sum_{i=1}^{k-1} F_i = F_{k+1}$$

many nodes.

### Growth of the Fibonacci numbers

#### Theorem 17

For all k > 0 we have:

$$F_k = \frac{1}{\sqrt{5}} \left( \frac{1+\sqrt{5}}{2} \right)^{k+1} - \frac{1}{\sqrt{5}} \left( \frac{1-\sqrt{5}}{2} \right)^{k+1}$$

The Fibonacci numbers grow exponentially.

Consequence:  $r_{\text{max}}(n) \in \mathcal{O}(\log n)$ .

# Summary of the running times

- merge, insert: constant time
- **delete-min**:  $\mathcal{O}(T + r_{\max}(n)) \subseteq \mathcal{O}(T + \log n)$ , where T is the current number of trees.
- **decrease-key**:  $\mathcal{O}(1) + \mathcal{O}(k)$   $(k \ge 1)$ , where at least k 2 markings are removed from the Fibonacci heap.

#### Definition 18

For a Fibonacci heap H we define its potential pot(H) as pot(H) := T + 2M, where T is its number of trees and M is the number of marked nodes.

For an operation op let  $\Delta_{pot}(op)$  be the difference of the potential after and before the execution of the operation.

$$\Delta_{pot}(op) = pot(\text{heap after } op) - pot(\text{heap before } op).$$

The amortized time of the operation is op is

$$t_{amort}(op) = t(op) + \Delta_{pot}(op)$$
.

The potential has the following properties:

- $pot(H) \ge 0$
- $pot(H) \in \mathcal{O}(|H|)$
- pot(nil) = 0

Let  $op_1, op_2, op_3, \ldots, op_m$  be sequence of m operations, and assume that the initial Fibonacci heap is empty.

We have

$$\sum_{i=1}^m t(op_i) \leq \sum_{i=1}^m t_{amort}(op_i).$$

Remark: The difference between these two sums is the potential of the generated Fibonacci heap.

Hence, it suffices to bound  $t_{amort}(op)$ .

**Convention:** By multiplying all terms in the following computations with a suitable constant, we can assume that

- merge and insert need one time step,
- that **delete-min** needs  $T + \log n$  time steps, and
- that **decrease-key** needs k + 1 time steps.

This allows to omit the  $\mathcal{O}$ -notation.

- $t_{amort}(merge) = t(merge) = 1$ , because the potential of the concatenation of two lists is the sum of the potentials of the two lists.
- $t_{amort}(insert) = t(insert) + \Delta_{pot}(op) = 1 + 1 = 2$ .
- For **delete-min** we have  $t(\text{delete-min}) \leq T + \log n$ , where T is the number of trees before the execution of **delete-min**.

After **delete-min** is the number of trees bounded by  $r_{max}(n)$ .

The number of marked nodes can only get smaller.

Hence, we have  $\Delta_{pot}(op) \leq r_{\max}(n) - T$  and  $t_{amort}(\mathbf{delete\text{-}min}) \leq T + \log n - T + r_{\max}(n) \in \mathcal{O}(\log n)$ .

• For **decrease-key** we have  $t(\text{decrease-key}) \le k+1 \ (k \ge 1)$ , where at least k-2 markings will be removed.

Moreover, k new trees are added to the Fibonacci heap. We get

$$\Delta_{pot}(op) = \Delta(T) + 2\Delta(M)$$
  
 $\leq k + 2 \cdot (2 - k)$   
 $= 4 - k$ 

and hence  $t_{amort}(\text{decrease-key}) \le k + 1 + 4 - k = 5 \in \mathcal{O}(1)$ .

#### Theorem 19

The following amortized time bounds hold for a Fibonacci heap:

```
t_{amort}(\mathbf{merge}) \in \mathcal{O}(1)

t_{amort}(\mathbf{insert}) \in \mathcal{O}(1)

t_{amort}(\mathbf{delete\text{-}min}) \in \mathcal{O}(\log n)

t_{amort}(\mathbf{decrease\text{-}key}) \in \mathcal{O}(1)
```

## Fibonacci heaps for Dijkstra

Back to Dijkstra's algorithm:

For Dijkstra's algorithm let V be the boundary and let key(v) be the current estimate for d(u, v).

Let n be the number of nodes and e be the number of edges of the input graph.

Dijkstra's algorithm will execute at most n insert-, e decrease-key- and n delete-min-operations.

# Fibonacci heaps for Dijkstra

$$t_{\mathsf{Dijkstra}} \leq n \cdot t_{amort}(\mathsf{insert}) \\ + e \cdot t_{amort}(\mathsf{decrease-key}) \\ + n \cdot t_{amort}(\mathsf{delete-min}) \\ \in \mathcal{O}(n + e + n \log n) \\ = \mathcal{O}(e + n \log n)$$

#### Remember that:

- with arrays we got  $t_{\text{Dijkstra}} \in \mathcal{O}(n^2)$ , and
- with standard heaps we got  $t_{\text{Dijkstra}} \in \mathcal{O}(e \log(n))$ .

## Idea of dynamic programming

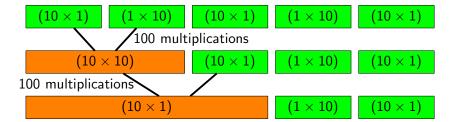

Compute a table of all subsolutions of a problem, until the overall solution is computed.

Every subsolutions is computed using the already existing entries in the table.

Dynamic programming is tightly related to backtracking.

In contrast to backtracking, dynamic programming used iteration instead of recursion. By storing computed subsolutions in table we avoid to solve the same subproblem several times.

$$(10\times1) \hspace{1cm} (1\times10) \hspace{1cm} (10\times1) \hspace{1cm} (1\times10) \hspace{1cm} (10\times1)$$

Multiplication from left to right:

In total: 400 multiplications

$$(10\times1) \hspace{1cm} (1\times10) \hspace{1cm} (10\times1) \hspace{1cm} (1\times10) \hspace{1cm} (10\times1)$$

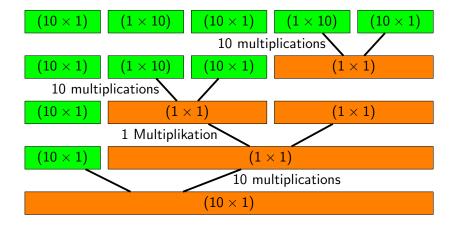

$$\begin{array}{c|cccc} \textbf{(10}\times\textbf{1)} & \textbf{(1}\times\textbf{10)} & \textbf{(10}\times\textbf{1)} & \textbf{(1}\times\textbf{10)} & \textbf{(10}\times\textbf{1)} \\ \hline \textbf{(10}\times\textbf{1)} & \textbf{(1}\times\textbf{10)} & \textbf{(10}\times\textbf{1)} & \textbf{(11}\times\textbf{10)} \\ \hline \textbf{(10}\times\textbf{1)} & \textbf{(10}\times\textbf{1)} & \textbf{(11}\times\textbf{10)} & \textbf{(11}\times\textbf{10)} \\ \hline \end{array}$$

Multiplication from right to left:

In total: 40 multiplications

$$\begin{array}{c|cccc} (10\times1) & \hline & (1\times10) & \hline & (10\times1) & \hline & (1\times10) & \hline & (10\times1) & \hline \end{array}$$

#### Multiplication in optimal order

In total: **31** multiplications

## Computing a long product of matrices

Let  $A_{(n,m)}$  be a matrix with n rows and m columns.

Assumption: Computing  $A_{(n,m)} := B_{(n,q)} \cdot C_{(q,m)}$  needs  $n \cdot q \cdot m$  scalar multiplications.

Input: sequence of matrices  $M^1_{(n_0,n_1)}, M^2_{(n_1,n_2)}, M^3_{(n_2,n_3)}, \dots, M^N_{(n_{N-1},n_N)}$ .

 $cost(M^1, ..., M^N) := minimal number of scalar multiplications in order to compute <math>M^1 \cdot ... M^N$  (minimum is taken over all possible bracketings).

Dynamic programming approach:

$$cost(M^{i},...,M^{j}) = min_{k}\{cost(M^{i},...,M^{k}) + cost(M^{k+1},...,M^{j}) + n_{i-1} \cdot n_{k} \cdot n_{j}\}$$

# Computing a long product of matrices

```
for i := 1 to N do
  cost[i, i] := 0;
  for i := i + 1 to N do
     cost[i, j] := \infty;
  endfor
endfor
for d := 1 to N-1 do
  for i := 1 to N - d do
    i := i + d;
     for k := i to i - 1 do
       t := \cos[i, k] + \cos[k + 1, j] + n[i - 1] \cdot n[k] \cdot n[j]
       if t < cost[i, j] then
          cost[i, j] := t;
          best[i, i] := k:
       endif
     endfor
  endfor
endfor
```

We will see a straightforward dynamic programming algorithm for computing optimal search trees with a running time of  $\Theta(n^3)$ .

An algorithm of Donald E. Knuth reduces the time to  $\Theta(n^2)$  ( $\rightarrow$  Algorithms II).

Let  $V = \{v_1, \dots, v_n\}$  be linearly ordered set of keys,  $v_1 < v_2 < \dots < v_n$ .

For every key  $v \in V$  we have given an access probability (also called the weight)  $\gamma(v)$ .

The idea is that with every key some additional information is associated (think about personnel numbers, and additional informations like name, birthday, salary, etc). Then  $\gamma(v_i)$  is the probability that the information associated with key  $v_i$  is accessed.

A binary search tree for  $v_1 < v_2 < \cdots < v_n$  is a binary tree with node set  $\{v_1, v_2, \dots, v_n\}$ , such that:

For every node v with left (resp., right) subtree L (resp. R) and all  $u \in L$ (resp.  $w \in R$ ) we have:  $u < v \ (v < w)$ .

Every node v of a search tree B has a level  $\ell_B(v)$ :  $\ell_B(v) := 1+$  distance (in number of edges) from v to root.

Finding a node at level  $\ell$  requires  $\ell$  comparisons (start in root and then walk down the path to the node).

Problem: Find a binary search tree *B* with minimal weighted inner path length

$$P(B) := \sum_{v \in V} \ell_B(v) \cdot \gamma(v).$$

The weighted inner path length is the average cost for accessing a node.

Dynamic programming works because subtrees of optimal binary search trees have to be optimal again.

#### Notation:

- node set =  $\{1, \ldots, n\}$ , i.e., we identify node  $v_i$  with i.
- P[i,j]: weighted inner path length of an optimal search tree for the node set  $\{i,\ldots,j\}$ .
- R[i,j]: root of an optimal search tree for  $\{i,\ldots,j\}$ . Since there might be several optimal search trees we take for R[i,j] for the largest root among all optimal search trees.
- $\Gamma[i,j] := \sum_{k=i}^{j} \gamma(k)$ : total weight of the node set  $\{i,\ldots,j\}$ .

# Computing optimal search trees in time $\mathcal{O}(n^3)$

Using dynamic programming we can compute all values P[i,j] and R[i,j].

For a binary search tree B with left subtree  $B_0$ , right subtree  $B_1$ , and total weight  $\Gamma(B)$  we have

$$P(B) := P(B_0) + P(B_1) + \Gamma(B).$$

We realize this idea with a cubic algorithm:

- $P[i,j] = \Gamma[i,j] + \min\{P[i,k-1] + P[k+1,j] \mid k \in \{i,\ldots,j\}\}$
- R[i,j] =largest key among all k for which P[i,k-1] + P[k+1,j] is minimal.

# Optimal search trees

```
\begin{array}{ll} \text{for } i := 1 \ \ \text{to } n \ \ \text{do} \\ P[i,i-1] := 0; \\ P[i,i] := \gamma(i); \\ \Gamma[i,i] := \gamma(i); \\ R[i,i] := i; \\ \text{endfor} \end{array}
```

```
for d := 1 to n-1 do
  for i := 1 to n - d do
    i := i + d;
     root := i:
     t := \infty:
     for k := i to i do
       if P[i, k-1] + P[k+1, j] \le t then
          t := P[i, k-1] + P[k+1, i];
          root := k:
       endif
     endfor
     \Gamma[i,j] := \Gamma[i,j-1] + \gamma(j);
     P[i,j] := t + \Gamma[i,j];
     R[i,j] := root;
  endfor
endfor
```

# Computation of regular expressions

Recall from GTI: Computation of regular expressions by Kleene.

A nondeterministic finite automaton (NFA) is a tuple

$$A = (Q, \Sigma, \delta \subseteq Q \times \Sigma \times Q, I, F)$$
 (w.l.o.g.  $Q = \{1, \dots, n\}$ ).

Let  $L^k[i,j]$  be the set of all words that label a path in A, which

- leads from i to j and
- thereby only visits intermediate states from  $\{1, ..., k\}$  (i and j do not necessarily belong to  $\{1, ..., k\}$ ).

Goal: Regular expressions for all  $L^n[i,j]$  with  $i \in I$  and  $j \in F$ .

We have

$$L^{0}[i,j] = \begin{cases} \{a \in \Sigma \mid (i,a,j) \in \delta\} & \text{if } i \neq j \\ \{a \in \Sigma \mid (i,a,j) \in \delta\} \cup \{\varepsilon\} & \text{if } i = j \end{cases}$$

$$L^{k}[i,j] = L^{k-1}[i,j] + L^{k-1}[i,k] \cdot L^{k-1}[k,k]^{*} \cdot L^{k-1}[k,j]$$

# Computation of regular expressions

### Algorithm Regular from an NFA

```
procedure NFA2REGEXP
Input: NEA A = (Q, \Sigma, \delta \subset Q \times \Sigma \times Q, I, F)
(Initialize: L[i,j] := \{a \mid (i,a,j) \in \delta \lor a = \varepsilon \land i = j\})
begin
  for k := 1 to n do
     for i = 1 to n do
        for i := 1 to n do
           L[i, j] := L[i, j] + L[i, k] \cdot L[k, k]^* \cdot L[k, j]
        endfor
     endfor
   endfor
end
```

# Computing the transitiv closure

### Algorithm Warshall-algorithm: computation of the transitive closure

```
procedure Warshall (var A : adjacency matrix)
Input: graph given by its adjacency matrix (A[i,j]) \in Bool_{n \times n}
begin
  for k := 1 to n do
    for i := 1 to n do
       for i := 1 to n do
         if (A[i, k] = 1) and (A[k, j] = 1) then
           A[i, j] := 1
         endif
       endfor
    endfor
  endfor
end
```

### Transitiv closure?

### **Algorithm** Is this algorithm correct?

```
procedure Warshall (var A : adjacency matrix)
Input: graph given by its adjacency matrix (A[i, j]) \in Bool_{n \times n}
begin
  for i := 1 to n do
    for j := 1 to n do
       for k := 1 to n do
         if (A[i, k] = 1) and (A[k, j] = 1) then
           A[i, j] := 1
         endif
       endfor
    endfor
  endfor
end
```

## Correctness of Warshall

Correctness of Warshall's algorithm follows from the following invariant:

- After the k-th excecution of the body of the **for**-loop, we have: A[i,j]=1, if there is a path from i to j with intermediate nodes from  $1,\ldots,k$ .
  - Important: the outermost loop runs over k!
- ② If A[i,j] is set to 1, then there exists a path from i to j.

If the 0/1-entries in the adjacency matrix are replaced from edge weights, one obtains Floyd's algorithm for computing shortest paths:

# Floyd-algorithm

### Algorithm Floyd: all shortest paths in a graph

```
procedure Floyd (var A : adjacency matrix)
Input: edge-weighted graph given by its adjacency matrix A[i,j] \in
  (\mathbb{N} \cup \infty)_{n \times n}, where A[i,j] = \infty means that there is no edge from i to j.
begin
  for k := 1 to n do
     for i := 1 to n do
       for i := 1 to n do
          A[i, j] := \min\{A[i, j], A[i, k] + A[k, j]\};
       endfor
     endfor
  endfor
```

end

# Floyd-algorithm

Floyd's algorithm computes correct results also for graphs with negative weights provide that there do not exist cycles with negative total weight.

Running time of Warshall and Floyd:  $\Theta(n^3)$ .

"Improvement" by testing before the j-loop, whether A[i,k]=1 (resp.,  $A[i,k]<\infty$ ) holds.

This yields a running time of  $\mathcal{O}(n^3)$ :

# Floyd's algorithm

## **Algorithm** Floyd's algorithm in $\mathcal{O}(n^3)$

```
procedure Floyd (var A : adjacency matrix)
Input: adjacency matrix A[i,j] \in (\mathbb{N} \cup \infty)_{n \times n}
begin
  for k := 1 to n do
     for i := 1 to n do
       if A[i, k] < \infty then
          for j := 1 to n do
             A[i, j] := \min\{A[i, j], A[i, k] + A[k, j]\};
          endfor
        endif
     endfor
  endfor
end
```

# Floyd's algorithm

### Algorithm Floyd's algorithm for negative cycles

```
procedure Floyd (var A : adjacency matrix)
Input: adjacency matrix A[i,j] \in (\mathbb{Z} \cup \{\infty, -\infty\})_{n \times n}
begin
  for k := 1 to n do
     for i = 1 to n do
       if A[i,k] < \infty then
          for j := 1 to n do
             if A[k,j] < \infty then
               if A[k, k] < 0 then A[i, j] := -\infty
                  else A[i, j] := \min\{A[i, j], A[i, k] + A[k, j]\}
                endif
             endif
  endfor endif endfor endfor
end
```

## Transitiv closure and matrix multiplication

Let  $A = (a_{i,j})_{1 \le i,j \le n}$  be the adjacency matrix of a directed graph with node set  $\{1,\ldots,n\}$ , i.e.,

$$a_{i,j} = \begin{cases} 1 & \text{if there is an edge from } i \text{ to } j \\ 0 & \text{otherwise} \end{cases}$$

Warshall's algorithm computes the reflexive and transitive closure  $A^*$  in time  $\mathcal{O}(n^3)$ .

Here,  $A^* = \sum_{k \geq 0} A^k$ , where  $A^0 = I_n$  is the identity matrix and  $\vee$  (boolean or) is taken for the addition of boolean matrices .

We add as follows: 0 + 0 = 0, 0 + 1 = 1 + 0 = 1 + 1 = 1.

By induction we get:  $A^k(i,j) = 1 \iff \exists$  path of length k from i to j.

This yields  $A^* = \sum_{k=0}^{n-1} A^k$ .

## Transitiv closure and matrix multiplication

Let  $B = I_n + A$ . We get  $A^* = B^m$  for all  $m \ge n - 1$ .

It therefore suffices to square the matrix  $\lceil \log_2(n-1) \rceil$  times in order to compute  $A^*$ .

Let M(n) be the time needed to multiply two boolean  $n \times n$ -matrices and let T(n) be the time needed to compute the reflexive and transitive closure.

We have

$$T(n) \in \mathcal{O}(M(n) \cdot \log n)$$
.

Using Strassen's algorithm, we get for all  $\varepsilon > 0$ :

$$T(n) \in \mathcal{O}(n^{\log_2(7)+\varepsilon}).$$

# Matrix multiplication ≤ transitiv closure

Under the plausible assumption that  $T(3n) \in \mathcal{O}(T(n))$  we get  $M(n) \in \mathcal{O}(T(n))$ :

For all boolean matrices A and B we have:

$$\left(\begin{array}{ccc} 0 & A & 0 \\ 0 & 0 & B \\ 0 & 0 & 0 \end{array}\right)^* = \left(\begin{array}{ccc} I_n & A & AB \\ 0 & I_n & B \\ 0 & 0 & I_n \end{array}\right).$$

Under the also plausible assumption that  $M(2n) \ge (2 + \varepsilon)M(n)$  for an  $\varepsilon > 0$ , we can show that also  $T(n) \in \mathcal{O}(M(n))$ .

Hence: The computation of the reflexive and transitive closure is up to constant factors equally expensive as matrix multiplication.

# Computation of the transitiv closure

## Input: $E \in \text{Bool}(n \times n)$

• Divide E into 4 submatrices A, B, C, D such that A and D are square matrices and each of the 4 matrices has size roughly  $n/2 \times n/2$ :

$$E = \left( \begin{array}{cc} A & B \\ C & D \end{array} \right).$$

- Compute recursively D\*:
  - Time: T(n/2).
- Compute  $F = A + BD^*C$ : Time:  $\mathcal{O}(M(n/2)) \leq \mathcal{O}(M(n))$ .
- Compute recursively  $F^*$ : Time: T(n/2).
- Set

$$E^* = \left(\begin{array}{c|c} F^* & F^*BD^* \\ \hline D^*CF^* & D^* + D^*CF^*BD^* \end{array}\right).$$

## Computation of the transitiv closure

We obtain the recurrence

$$T(n) \le 2T(n/2) + c \cdot M(n)$$
 for some  $c > 0$ .

This yields

$$T(n) \le c \cdot \left(\sum_{i \ge 0} 2^i \cdot M(n/2^i)\right)$$
 (by induction)  
 $\le c \cdot \sum_{i \ge 0} \left(\frac{2}{2+\varepsilon}\right)^i \cdot M(n)$  (da  $M(n/2) \le \frac{1}{2+\varepsilon}M(n)$ )  
 $\in \mathcal{O}(M(n))$ .

The best current algorithm for multiplying two  $(n \times n)$ -matrices needs approx.  $\Theta(n^{2,372873...})$  many arithmetic operations (Virginia Vassilevska Williams 2014).

#### Conjecture

For every  $\epsilon > 0$  there exists an algorithm for multiplying two  $(n \times n)$ -matrices in time  $O(n^{2+\varepsilon})$ .

Assume now that we have three  $(n \times n)$ -matrices A, B and C.

How many arithmetic operations are needed to test whether  $A \cdot B = C$ holds?

Trivial answer:  $O(n^{2,372873...})$ 

But there is a better method!

### Satz 20 (Korec, Wiedermann 2014)

Let A, B, C be  $(n \times n)$ -matrices with entries from  $\mathbb{Z}$ . Using  $O(n^2)$  many operations we can check whether  $A \cdot B = C$  holds.

#### Proof: Let

$$A = (a_{i,j})_{1 \leq i,j \leq n},$$

$$B = (b_{i,j})_{1 \leq i,j \leq n},$$

$$C = (c_{i,i})_{1 \leq i,j \leq n}$$
 and

$$D = (d_{i,i})_{1 \leq i,i \leq n} = A \cdot B - C.$$

Thus, we have  $A \cdot B = C$  if and only if D is the zero-matrix.

Let x be real-valued variable and consider the column-vector

$$v = (1, x, x^2, \dots, x^{n-1})^T$$
.

Hence,  $D \cdot v = A \cdot B \cdot v - C \cdot v$  is a column-vector whose *i*-th entry is the polynomial

$$p_i(x) = d_{i,1} + d_{i,2}x + d_{i,3}x^2 + \cdots + d_{i,n}x^{n-1}.$$

We therefore have  $A \cdot B = C$  if and only if  $p_i(x)$  is the zero polynomial for all 1 < i < n.

We use the following theorem:

### Cauchy bound

Let  $p(x) = a_n x^n + a_{n-1} x^{n-1} + \cdots + a_1 x + a_0 \in \mathbb{R}[x]$  be not the zero-polynomial and  $a_n \neq 0$ . For every  $\alpha$  with  $p(\alpha) = 0$  we have

$$|\alpha| < 1 + \frac{\max\{|a_i| \mid 0 \le i \le n-1\}}{|a_n|}.$$

#### **Proof of the Cauchy bound:**

By replacing p(x) by the polynomial  $x^n + \frac{a_{n-1}}{a_n}x^{n-1} + \cdots + \frac{a_1}{a_n}x + \frac{a_0}{a_n}$ , it suffices to prove the Cauchy bound for the case  $a_n = 1$ .

Let 
$$p(x) = x^n + a_{n-1}x^{n-1} + \cdots + a_1x + a_0$$
 and

$$h=\max\{|a_i|\mid 0\leq i\leq n-1\}.$$

Assume that 
$$p(\alpha) = \alpha^n + a_{n-1}\alpha^{n-1} + \cdots + a_1\alpha + a_0 = 0$$
, i.e.,

$$\alpha^n = -a_{n-1}\alpha^{n-1} - \cdots - a_1\alpha - a_0.$$

We show that  $|\alpha| < 1 + h$ .

If 
$$|\alpha| \le 1$$
, we have  $|\alpha| < 1 + h$  (if  $h = 0$  then we must have  $\alpha = 0$ ).

Now assume that  $|\alpha| > 1$ .

We get

$$|\alpha|^{n} \leq |a_{n-1}| \cdot |\alpha|^{n-1} + \dots + |a_{1}| \cdot |\alpha| + |a_{0}|$$
  
$$\leq h \cdot (|\alpha|^{n-1} + \dots + |\alpha| + 1)$$
  
$$= h \cdot \frac{|\alpha|^{n} - 1}{|\alpha| - 1}.$$

Since  $|\alpha| > 1$ , we obtain:

$$|\alpha| - 1 \le h \cdot \frac{|\alpha|^n - 1}{|\alpha|^n} < h$$

Let  $a = \max\{|a_{i,j}| | 1 \le i, j \le n\}, b = \max\{|b_{i,j}| | 1 \le i, j \le n\}$  and  $c = \max\{|c_{i,i}| \mid 1 \le i, j \le n\}.$ 

The absolute values of the coefficients of the polynomials  $p_i(x)$  can be bounded as follows:

$$|d_{i,j}| = |\sum_{k=1}^n a_{i,k} b_{k,j} - c_{i,j}| \le \sum_{k=1}^n |a_{i,k}| \cdot |b_{k,j}| + |c_{i,j}| \le n \cdot a \cdot b + c.$$

Let  $d = n \cdot a \cdot b + c$  and r = 1 + d.

The Cauchy bound yields for all  $1 \le i \le n$ :

$$p_i(x) = 0 \Leftrightarrow p_i(r) = 0$$

**Note:** It is easy to get an upper bound d for the absolute values of the entries of D, but it is not so clear how to get a lower bound.

But: Since A, B, C are matrices over  $\mathbb{Z}$ , we have  $p_i(x) \in \mathbb{Z}[x]$ .

Therefore, the absolute value of the leading coefficient of  $p_i(x)$  is at least 1, if  $p_i(x)$  is not the zero-polynomial.

We can therefore check with the following algorithm, whether  $A \cdot B = C$ :

- ① Compute  $a = \max\{|a_{i,j}|\}, b = \max\{|b_{i,j}|\}, c = \max\{|c_{i,j}|\}$  and  $r = 1 + n \cdot a \cdot b + c$  $(3n^2 \text{ many comparisons}, 2 \text{ additions}, 2 \text{ multiplications})$
- **2** Compute the column vector  $u = (1, r, r^2, \dots, r^{n-1})^T$ . (n-2 multiplications)
- **3** Compute  $p := B \cdot u$ ,  $s := A \cdot p$  and  $t := C \cdot u$  $(O(n^2)$  many arithmetic operations)
- $A \cdot B = C$  if and only if s = t.
